PREFACE

From the time Dr. Phil Cooper handed me a copy of Volume 9 of *Systemic Pathology: The Skin* by David Weedon, published in 1992, I realized that here indeed was a work of distinction, different from any other I had encountered: exquisitely thorough in detail but also filled with practical diagnostic advice. I eagerly sought the subsequent editions (the second edition quickly became worn out and had to be rebound; the third is well on its way to the same fate), using them in teaching dermatology and pathology residents and dermatopathology fellows. Little did I know that I would one day be preparing the fourth edition. Despite the familiarity with the book one develops through teaching with it and using it in daily practice, one gains a completely different perspective when actually editing and updating such a work. It was through that effort that I came to fully appreciate the significance of Dr. Weedon's monumental achievement in creating *Skin Pathology*, which in its way, in my view, ranks with Osler's *Principles and Practice of Medicine*, first published more than a century ago (1892).

And that's when the pressure *really* begins! One quickly realizes the need to maintain the overall high quality, scientific accuracy, and style that have become so familiar but also to make the kinds of meaningful changes that can keep the book fresh and up-to-date while at the same time not adding so much material that the work is bogged down in detail and becomes impractical. It is my hope that, to some extent, this goal has been achieved.

On first opening this volume, I hope that regular readers will have that comfortable sense of familiarity with the organization and writing style. Despite the advances of the past 4 or 5 years, much of the basic information about cutaneous diseases remains valid, and certainly much of the descriptive histopathology of established disorders remains the same. For the most part, I have also left the opinions on certain dermatopathologic controversies intact (e.g., the issue of 'hypersensitivity dermatitis') because on the majority of these issues we are in full agreement. So the book ought to read pretty much as one would expect 'Weedon' to read!

On the other hand, there are clearly some changes. First and foremost, of course, are updates on cutaneous diseases based on the literature of the past 4 or 5 years. The output of scientific information in this short period of time has been nothing less than extraordinary; for some diseases, there are literally thousands of new references, contributed by clinicians and scientists throughout the globe. A large part of the author's/editor's task is to make a decision as to which studies should be included and which should not. Reviews of recent advances, breakthroughs in the understanding of diseases at the molecular level, and new methods of enhancing diagnostic accuracy obviously receive priority. The bar is set higher for inclusion of case reports, but these, too, are cited when they provide significant insights into a disease or when, for example, they show that a disease occurs in a particular anatomic site more often than expected, or that a previously overlooked histopathologic finding can be of significant diagnostic importance.

Second, I have placed increasing emphasis on differential diagnosis, which was always there, of course, but embedded in the general histopathology discussion. Differential diagnosis has now been promoted to a separate section, with a heading at the same level as 'Histopathology.' The information in these sections has been extracted from other portions of the text, from my own experience, and from

recent literature focused on this topic. It is hoped that this will make diagnostically useful information more readily accessible when working at the microscope. Third, it is my belief that every bit of information that can contribute in any way to the diagnostic process ought to be included in this text. Therefore, there are short sections on the features seen on fine needle aspiration cytology, dermoscopy, and confocal laser microscopy; these are usually found, but set apart, in the Histopathology sections. Fourth, I have de-emphasized the sections on therapy. These are still included because an all-important fact is that therapeutic intervention changes the microscopic appearance of cutaneous disease, placing a particular burden on the pathologist when the 'classic' features of a disease are not present! The therapy sections for the most part no longer appear under a separate heading but are included, usually, as the last paragraph in the general discussion of a disease entity. They consist largely of lists of therapeutic agents, without detailed analyses of risks and benefits – it being believed that this information is presented in greater detail in volumes devoted to clinical dermatology and therapeutics. Fifth, a number of new figures have been added – 425 in all, or an average of more than 10 per chapter.

Although the organization of chapters is largely the same as in the previous edition, in two instances significant changes have been made. Many of the sections on melanoma in Chapter 32 (Lentiginos, Nevi, and Melanomas) have been extensively rewritten by Dr. Gregory A. Hosler. These include Incidence and Mortality, Risk Factors, Pathogenesis, Classification, Special Techniques to Aid Diagnosis, Prognostic Factors and Survival, and Management. In Chapter 33 (Tumors of Cutaneous Appendages), the grouping of conditions has been changed, and in particular apocrine and eccrine tumors are combined into one section. This is done largely for the convenience of the reader; thus, the poroma group is discussed together, as are the hidradenomas (apocrine and poroid). Current information about the lines of differentiation of these tumors is still provided – but with the realization that the 'final word' vis-à-vis apocrine versus eccrine differentiation probably has yet to be written! Newly reported drugs or other agents producing various dermatoses (e.g., acute generalized exanthematous pustulosis, lichenoid drug eruptions, and pityriasisiform eruptions) have been added to sections and tables in the relevant chapters. It is the nature of the subject of drug reactions that much of this information is scattered throughout the text. Thus, the actual chapter on cutaneous drug reactions (Chapter 20) has been focused on a general discussion of drug reactions, a review of major categories of offending drugs, and a consideration of a few unique types of eruptions (e.g., the halogenoderma) while providing page references to the other types of eruptions considered elsewhere in the text. That organization is retained in this edition, in part to avoid needless duplication of information.

I express my gratitude to Dr. Gregory Hosler for his excellent updated sections on melanoma and to Dr. Mark R. Wick for his contribution of several figures, including fluorescent *in situ* hybridization (FISH) images. I also wish to thank Dr. Geoffrey Strutton for his original contributions to the chapters on Vascular Tumors and Cutaneous Infiltrates – Lymphomatous and Leukemic. My deep appreciation goes to Michael Houston, Executive Content Strategist for Elsevier Ltd., and Nani Clansey, Humayra Rahman-Khan, Joanna Souch, Dan Hays, and Susan Stuart for their patience and help in the production of this volume.

To Julie and Wyatt, with love and gratitude for their support,
and to David Weedon, with the utmost admiration and respect.

An approach to the interpretation of skin biopsies

INTRODUCTION

Dermatopathology requires years of training and practice to attain an acceptable level of diagnostic skill. Many have found this process an exciting and challenging one, well worth the expenditure of time and intellectual effort. To the trainee, there seems to be an endless number of potential diagnoses in dermatopathology, with many bewildering names. However, if a logical approach is adopted, the great majority of skin biopsies can be diagnosed specifically and the remainder can be partly categorized into a particular group of diseases. This learning process can be enhanced under the tutelage of a skilled mentor and by 'optical mileage', a term used for the self-examination and diagnosis of large amounts of day-to-day material; such cases invariably differ from 'classic' examples of an entity found in teaching sets. It should not be forgotten that the histopathological features of some dermatoses are not diagnostically specific, and it may only be possible in these circumstances to state that the histopathological features are 'consistent with' the clinical diagnosis.

The interpretation of many skin biopsies requires the identification and integration of two different, morphological features – the *tissue reaction pattern* and the *pattern of inflammation*. This is a crude algorithmic approach; more sophisticated ones usually hinder rather than enhance the ability to make a specific diagnosis.

Tissue reaction patterns are distinctive morphological patterns that categorize a group of cutaneous diseases. Within each of these histopathological categories there are diseases that may have similar or diverse clinical appearances and etiologies. Some diseases may show histopathological features of more than one reaction pattern at a particular time or during the course of their evolution. Such cases may be difficult to diagnose. In this edition, an attempt has been made to list diseases that characteristically express more than one tissue reaction pattern (presented later).

The *pattern of inflammation* refers to the distribution of the inflammatory cell infiltrate within the dermis and/or the subcutaneous tissue. There are several distinctive patterns of inflammation (discussed later): their recognition assists in making a specific diagnosis.

Some dermatopathologists base their diagnostic approach on the inflammatory pattern, whereas others look first to see if the biopsy can be categorized into one of the 'tissue reactions' and use the pattern of inflammation to further categorize the biopsy within each of these reaction patterns. In practice, the experienced dermatopathologist sees these two aspects (tissue reaction pattern and inflammatory pattern) simultaneously, integrating and interpreting the findings in a matter of seconds. For trainees in dermatopathology, the use of tissue reaction patterns, combined with the mnemonic for diseases with a superficial and deep inflammatory pattern, appears to be the easiest method to master.

The categorization of inflammatory dermatoses by their tissue reactions is considered first.

Tissue reaction patterns

There are many different reaction patterns in the skin, but the majority of inflammatory dermatoses can be categorized into six different patterns. For convenience, these are called the *major tissue reaction patterns*. Occasionally, diseases express more than one major pattern, either *ab initio* or during their evolution. They are dealt with separately in the 'Combined reaction patterns' section. There are a number of other diagnostic reaction patterns that occur much less commonly than the major group of six but that are nevertheless specific for other groups of dermatoses. These patterns are referred to as *minor tissue reaction patterns*. They are considered after the major reaction patterns.

Patterns of inflammation

There are four patterns of cutaneous inflammation characterized on the basis of distribution of inflammatory cells within the skin:

1. Superficial perivascular inflammation
2. Superficial and deep dermal inflammation
3. Folliculitis and perifolliculitis
4. Panniculitis.

There are numerous dermatoses showing a superficial perivascular inflammatory infiltrate in the dermis and a limited number in the other categories. Sometimes panniculitis and folliculitis are regarded as major tissue reaction patterns because of their easily recognizable pattern.

MAJOR TISSUE REACTION PATTERNS

A significant number of inflammatory dermatoses can be categorized into one of the following six major reaction patterns, the key morphological feature of which is included in parentheses:

1. *Lichenoid* (basal cell damage; interface dermatitis)
2. *Psoriasiform* (regular epidermal hyperplasia)
3. *Spongiform* (intraepidermal intercellular edema)
4. *Vesiculobullous* (blistering within or beneath the epidermis)
5. *Granulomatous* (chronic granulomatous inflammation)
6. *Vasculopathic* (pathological changes in cutaneous blood vessels).

Each of these reaction patterns is discussed in turn, together with a list of the dermatoses found in each category.

THE LICHENOID REACTION PATTERN (‘INTERFACE DERMATITIS’)

The lichenoid reaction pattern ('interface dermatitis') (see Chapter 3) is characterized by *epidermal basal cell damage*, which may be manifested by cell death and/or basal vacuolar change (known in the past as 'liquefaction degeneration'). The basal cell death usually presents in the form of shrunken eosinophilic cells, with pyknotic nuclear remnants, scattered along the basal layer of the epidermis (**Fig. 1.1**). These cells are known as Civatte bodies. They are undergoing death by apoptosis, a morphologically distinct type of cell death seen in both physiological and pathological circumstances (see p. 38). Sometimes the basal cell damage is quite subtle, with only an occasional Civatte body and very focal vacuolar change. This is a feature of some drug reactions.

In the United States, the term '**interface dermatitis**' is used synonymously with the lichenoid reaction pattern, although it is not usually applied to the subtle variants. Its use in other countries is by no means universal. At other times, it is used for the morphological subset (discussed later) in which inflammatory cells extend into the basal layer or above. The term is widely used despite its lack of precision. It is warmly embraced as a diagnosis, but it is nothing more than a pattern, encompassing many clinical entities with diverse presentations, etiologies, and treatments.

A distinctive subgroup of the lichenoid reaction pattern is the *poikilodermatous pattern*, characterized by mild basal damage, usually of vacuolar type, associated with epidermal atrophy, pigment incontinence, and dilatation of vessels in the papillary dermis (**Fig. 1.2**). It is a feature of the various types of poikiloderma (see p. 75).

The specific diagnosis of a disease within the lichenoid tissue reaction requires an assessment of several other morphological features, including the following:

Figure 1.1 The lichenoid reaction pattern. (A) There are shrunken keratinocytes with pyknotic nuclear remnants (Civatte bodies) in the basal layer. These cells are undergoing death by apoptosis. (B) There is also focal vacuolar change. (H&E)

Figure 1.2 The poikilodermatous variant of the lichenoid reaction pattern. It is characterized by mild vacuolar change of the basal layer of the epidermis, mild epidermal atrophy, and dilatation of vessels in the papillary dermis. (H&E)

1. The *type of basal damage* (vacuolar change is sometimes more prominent than cell death in lupus erythematosus, dermatomyositis, the poikilodermas, and drug reactions)
2. The *distribution of the accompanying inflammatory cell infiltrate* (the infiltrate touches the undersurface of the basal layer in lichen planus and its variants, early lichen sclerosus et atrophicus, and in disseminated superficial actinic porokeratosis; it obscures the dermoepidermal interface (so-called 'interface dermatitis') in erythema multiforme, paraneoplastic pemphigus, fixed drug eruptions, acute pityriasis lichenoides (PLEVA), acute graft-versus-host disease (GVHD), one variant of lupus erythematosus, and reactions to phenytoin (Dilantin®) and other drugs; and it involves the deep as well as the superficial part of the dermis in lupus erythematosus, syphilis, photolichenoid eruptions, and some drug reactions)
3. The presence of *prominent pigment incontinence* (as seen in drug reactions, the poikilodermas, lichenoid reactions in dark-skinned people, and some of the sun-exacerbated lichen planus variants, such as lichen planus actinicus)
4. The presence of *satellite cell necrosis* (lymphocyte-associated apoptosis) – defined here as two or more lymphocytes in close proximity to a Civatte body (a feature of graft-versus-host reaction, regressing plane warts, subacute radiation dermatitis, erythema multiforme, and some drug reactions).

The diseases showing the lichenoid reaction pattern are listed in [Table 1.1](#).

THE PSORIASIFORM REACTION PATTERN

From a morphological standpoint, the psoriasiform tissue reaction (see Chapter 4) is defined as *epidermal hyperplasia in which there is elongation of the rete ridges, usually in a regular manner* ([Fig. 1.3](#)).

It is acknowledged that this approach has some shortcomings because many of the diseases in this category, including psoriasis, show no significant epidermal hyperplasia in their early stages. Rather, dilated vessels in the papillary dermis and an overlying suprapapillary scale may be the dominant features in early lesions of psoriasis. Mitoses are increased in basal keratinocytes in this pattern, particularly in active lesions of psoriasis.

The psoriasiform reaction pattern was originally defined as the cyclic formation of a suprapapillary exudate with focal parakeratosis

related to it. The concept of the 'squirting dermal papilla' was also put forward with the suggestion that serum and inflammatory cells escaped from the blood vessels in the papillary dermis and passed through the epidermis to form the suprapapillary exudate referred to previously. This 'concept', although outmoded, is useful in considering early lesions of psoriasis in which dilated vessels and surface suprapapillary scale are often the only features. The epidermal hyperplasia that also

occurs was regarded as a phenomenon secondary to these other processes.

Diseases showing the psoriasiform reaction pattern are listed in Table 1.2.

THE SPONGIOTIC REACTION PATTERN

The spongiotic reaction pattern (see Chapter 5) is characterized by *intraepidermal intercellular edema (spongiosis)*. It is recognized by the

Figure 1.4 The spongiotic reaction pattern. There is mild intercellular edema with elongation of the intercellular bridges. (H&E)

Figure 1.5 The spongiotic reaction pattern in a lesion of some duration. Psoriasiform hyperplasia coexists with the spongiosis. (H&E)

presence of widened intercellular spaces between keratinocytes, with elongation of the intercellular bridges (**Fig. 1.4**). The spongiosis may vary from microscopic foci to grossly visible vesicles. This reaction pattern has been known in the past as the ‘eczematous tissue reaction’. Inflammatory cells are present within the dermis, and their distribution and type may aid in making a specific diagnosis within this group. This is the most difficult reaction pattern in which to make a specific clinicopathological diagnosis; often a diagnosis of ‘spongiotic reaction consistent with ...’ is all that can be made.

The major diseases within this tissue reaction pattern (atopic dermatitis, allergic and irritant contact dermatitis, nummular dermatitis, and seborrheic dermatitis) all show progressive psoriasiform hyperplasia of the epidermis with chronicity (**Fig. 1.5**). This change is usually accompanied by diminishing spongiosis, but this will depend on the activity of the disease. Both patterns may be present in the same biopsy. The psoriasiform hyperplasia is, in part, a response to chronic rubbing and scratching.

Six patterns of spongiosis can be recognized:

1. *Neutrophilic spongiosis* (where there are neutrophils within foci of spongiosis)

Figure 1.6 Epidermal spongiosis combined with subepidermal edema. This combination characterizes a certain group of diseases. (H&E)

2. *Eosinophilic spongiosis* (where there are numerous eosinophils within foci of spongiosis)
3. *Miliarial (acrosyringial) spongiosis* (where the edema is related to the acrosyringium)
4. *Follicular spongiosis* (where the spongiosis is centered on the follicular infundibulum)
5. *Pityriasiform spongiosis* (where the spongiosis forms small vesicles containing lymphocytes, histiocytes, and Langerhans cells)
6. *Haphazard spongiosis* (the other spongiotic disorders in which there is no particular pattern of spongiosis).

The diseases showing the spongiotic reaction pattern are listed in **Table 1.3(a)**.

A seventh pattern, which is really a variant of haphazard spongiosis, combines epidermal spongiosis with subepidermal edema (**Fig. 1.6**), which can vary from mild to severe, even forming subepidermal blisters. Its causes are listed in **Table 1.3(b)**.

THE VESICULOBULLOUS REACTION PATTERN

In the vesiculobullous reaction pattern, there are *vesicles or bullae at any level within the epidermis or at the dermoepidermal junction* (see Chapter 6). A specific diagnosis can usually be made in a particular case by assessing three features – the anatomical level of the split, the underlying mechanism responsible for the split, and, in the case of subepidermal lesions, the nature of the inflammatory infiltrate in the dermis.

The *anatomical level of the split* may be subcorneal, within the stratum malpighii, suprabasal or subepidermal. The *mechanism responsible* for vesiculation may be exaggerated spongiosis, intracellular edema and ballooning (as occurs in viral infections such as herpes simplex), or acantholysis. Acantholysis is the loss of coherence between epidermal cells. It may be a primary phenomenon or secondary to inflammation, ballooning degeneration (as in viral infections of the skin), or epithelial dysplasia. In the case of subepidermal blisters, electron microscopy and immunoelectron microscopy could be used to make a specific diagnosis in most cases. In practice, the subepidermal blisters are subdivided on the basis of the *inflammatory cell infiltrate within the dermis* (**Fig. 1.7**). Knowledge of the immunofluorescence findings is often helpful in categorizing the subepidermal blistering diseases.

Table 1.4 lists the various vesiculobullous diseases, based on the anatomical level of the split and, in the case of subepidermal lesions, the predominant inflammatory cell within the dermis.

Table 1.3(a) Diseases showing the spongiotic reaction pattern

Neutrophilic spongiosis	Nummular dermatitis
Pustular psoriasis/Reiter's syndrome	Lichen striatus (uncommonly)
Prurigo pigmentosa	Gianotti–Crosti syndrome (sometimes)
IgA pemphigus	Other spongiotic disorders
Infantile acropustulosis	Irritant contact dermatitis
Acute generalized exanthematous pustulosis	Allergic contact dermatitis
Palmoplantar pustulosis	Nummular dermatitis
Staphylococcal toxic shock syndrome	Sulzberger–Garbe syndrome
Neisserial infections	Seborrheic dermatitis
Dermatophytosis/candidosis	Atopic dermatitis
Beetle (<i>Paederus</i>) dermatitis	Papular dermatitis
Pustular contact dermatitis	Pompholyx
Glucagonoma syndrome	Unclassified eczema
Amicrobial pustuloses	Hyperkeratotic dermatitis of the hands
Periodic fever syndromes	Juvenile plantar dermatosis
Eosinophilic spongiosis	Vein graft donor-site dermatitis
Pemphigus (precursor lesions)	Stasis dermatitis
Herpetiform pemphigus	Autoeczematization ('id' reaction)
Pemphigus vegetans	Dermal hypersensitivity reaction/urticarial dermatitis
Bullous pemphigoid/cicatricial pemphigoid	Pityriasis rosea
Herpes gestationis	Papular acrodermatitis of childhood
Idiopathic eosinophilic spongiosis	Spongiotic drug reactions
Eosinophilic, polymorphic, and pruritic eruption	Autoimmune progesterone dermatitis
Allergic contact dermatitis	Estrogen dermatitis
Protein contact dermatitis	Chronic superficial dermatitis
Atopic dermatitis	Perioral dermatitis
Arthropod bites	Blaschko dermatitis
Eosinophilic folliculitis	Psoriasis (spongiotic and site variants)
Incontinentia pigmenti (first stage)	Light reactions (particularly polymorphic light eruption)
Drug reactions	Dermatophytoses
'Id' reaction	Arthropod bites
Still's disease	Grover's disease (spongiotic variant)
Wells' syndrome	Toxic shock syndrome
Miliarial spongiosis	PUPPP
Miliaria (may look pityriasiform on random section)	Herpes gestationis (early)
Follicular spongiosis	Erythema annulare centrifugum (not always pityriasiform)
Infundibulofolliculitis	Figurate erythemas
Atopic dermatitis (follicular lesions)	Pigmented purpuric dermatoses
Apocrine miliaria	Pityriasis alba
Eosinophilic folliculitis	Ecematoid GVHD
Follicular mucinosis	Allograft rejection
Infectious folliculitides	Eruption of lymphocyte recovery
Perioral dermatitis	Lichen striatus
Pityriasiform spongiosis	Lichen simplex chronicus
Pityriasis rosea	Sweet's syndrome
Pityriasiform drug reaction	Erythroderma
Erythema annulare centrifugum	Mycosis fungoides
Allergic contact dermatitis	Acrokeratosis paraneoplastica

Table 1.3(b) Diseases showing spongiosis and subepidermal edema

Arthropod bites and bite-like reactions in lymphoma
Cercarial dermatitis/larva migrans
PUPPP
Autoeczematization
Superantigen 'id' reaction
Allergic contact dermatitis ('dermal type')
Contact urticaria, papular urticaria
Dermal hypersensitivity/urticarial dermatitis
Erysipelas, erysipeloid
Dermatophytoses
Prebullous pemphigoid
Sweet's syndrome
Wells' syndrome
Miliaria rubra
Pompholyx
Polymorphic light eruption
Spongiotic drug reactions (including estrogen/progesterone dermatitis)

Figure 1.7 The vesiculobullous reaction pattern. In this case, the blister is subepidermal, so further characterization of it requires an assessment of the inflammatory cell infiltrate within the dermis – in this case, neutrophils. (H&E)

THE GRANULOMATOUS REACTION PATTERN

This group of diseases (see Chapter 7) is characterized by the presence of *chronic granulomatous inflammation* – that is, localized collections of epithelioid cells usually admixed with giant cells, lymphocytes, plasma cells, fibroblasts, and nonepithelioid macrophages (Fig. 1.8). Five histological types of granuloma can be identified on the basis of the constituent cells and other changes within the granulomas: sarcoidal, tuberculoid, necrobiotic (collagenolytic), suppurative, and foreign body. A miscellaneous category is usually added to any classification.

Clinically, granulomas present like most other dermal infiltrates, with a mass that is usually firm and is detectable below the skin surface (epidermis) and usually moveable over the deeper tissues. As such,

Figure 1.8 The granulomatous reaction pattern. A small tuberculoid granuloma is present in the dermis. (H&E)

the clinical differential diagnoses include cutaneous tumors and lymphocytic infiltrates.

Sarcoidal granulomas are composed of epithelioid cells and giant cells, some containing asteroid bodies or other inclusions. The granulomas are often referred to as 'naked granulomas', in that they have only a sparse 'clothing' of peripheral lymphocytes and plasma cells, in contrast to tuberculoid granulomas that usually have more abundant lymphocytes. Some overlap occurs between sarcoidal and tuberculoid granulomas.

Tuberculoid granulomas resemble those seen in tuberculosis, although caseation necrosis is not always present. The giant cells that are present within the granuloma are usually of Langhans type.

Necrobiotic (collagenolytic) granulomas are composed of epithelioid cells, lymphocytes, and occasional giant cells associated with areas of 'necrobiosis' of collagen. Sometimes the inflammatory cells are arranged in a palisade around the areas of necrobiosis. The term 'necrobiosis' has been criticized because it implies that the collagen (which is not a vital structure) is 'necrotic'. Accordingly, the term 'collagenolytic' is now preferred. The process of collagenolysis is characterized by an accumulation of acid mucopolysaccharides between the collagen bundles and degeneration of some interstitial fibroblasts and histiocytes.

Table 1.4 Vesiculobullous diseases	
Intracorneal and subcorneal blisters	Subepidermal blisters with lymphocytes
Peeling skin syndrome	Erythema multiforme
Adult Still's disease	Paraneoplastic pemphigus
Impetigo	Bullous fixed drug eruption
Staphylococcal 'scalded skin' syndrome	Lichen sclerosus et atrophicus
Dermatophytosis	Lichen planus pemphigoides
Pemphigus foliaceus and erythematosus	Polymorphic light eruption
Herpetiform pemphigus	Fungal infections
Subcorneal pustular dermatosis	Dermal allergic contact dermatitis
IgA pemphigus	Bullous leprosy
Infantile pustular dermatoses	Bullous mycosis fungoides
Acute generalized exanthematous pustulosis	Subepidermal blisters with eosinophils*
Miliaria crystallina	Wells' syndrome
Intraepidermal (stratum malpighii) blisters	Bullous pemphigoid
Spongiotic blistering diseases	Pemphigoid gestationis
Palmoplantar pustulosis	Arthropod bites (in sensitized individuals)
Amicrobial pustulosis of autoimmune diseases	Drug reactions
Erosive pustular dermatosis of leg	Epidermolysis bullosa
Viral blistering diseases	Subepidermal blisters with neutrophils*
Epidermolysis bullosa simplex (localized type)	Dermatitis herpetiformis
Friction blister	Linear IgA bullous dermatosis
Suprabasilar blisters	Mucous membrane pemphigoid
Pemphigus vulgaris and vegetans	Ocular cicatricial pemphigoid
Paraneoplastic pemphigus	Localized cicatricial pemphigoid
Hailey–Hailey disease	Deep lamina lucida (anti-p105) pemphigoid
Darier's disease	Anti-p200 pemphigoid
Grover's disease	Bullous urticaria
Acantholytic solar keratosis	Bullous acute vasculitis
Subepidermal blisters with little inflammation	Bullous lupus erythematosus
Epidermolysis bullosa	Erysipelas
Porphyria cutanea tarda and pseudoporphyria	Sweet's syndrome
Bullous pemphigoid (cell-poor variant)	Epidermolysis bullosa acquisita
Burns and cryotherapy	Subepidermal blisters with mast cells
Toxic epidermal necrolysis	Bullous urticaria pigmentosa
Suction blisters	Miscellaneous blistering diseases
Blisters overlying scars	Drug overdose-related bullae
Bullous solar elastosis	Methyl bromide-induced bullae
Bullous amyloidosis	Etretinate-induced bullae
Waldenström's macroglobulinemia	PUVA-induced bullae
Drug reactions	Cancer-related bullae
Kindler's syndrome	Lymphatic bullae
	Bullous eruption of diabetes mellitus

*Varying admixtures of eosinophils and neutrophils may be seen in cicatricial pemphigoid and late lesions of dermatitis herpetiformis.

Suppurative granulomas have neutrophils within and sometimes surrounding the granuloma. The granulomatous component is not always well formed.

Foreign body granulomas have multinucleate, foreign body giant cells as a constituent of the granuloma. Foreign material can usually be visualized in sections stained with hematoxylin and eosin (H&E),

although at other times it requires the use of polarized light for its detection.

The identification of organisms by the use of special stains (the periodic acid–Schiff (PAS) and other stains for fungi and stains for acid-fast bacilli) or by culture may be necessary to make a specific diagnosis. Organisms are usually scanty in granulomas associated with

Reactions to foreign materials and vaccines	
Crohn's disease	

infectious diseases. The distribution of the granulomas (they may be arranged along nerve fibers in tuberculoid leprosy) may assist in making a specific diagnosis.

Note that many of the infectious diseases listed in [Table 1.5](#) as causing the granulomatous tissue reaction can also produce inflammatory reactions that do not include granulomas, depending on the stage of the disease and the immune status of the individual.

THE VASCULOPATHIC REACTION PATTERN

The vasculopathic reaction pattern (see Chapter 8) includes a clinically heterogeneous group of diseases that have in common *pathological changes in blood vessels*. The most important category within this tissue reaction pattern is *vasculitis*, which can be defined as an inflammatory process involving the walls of blood vessels of any size ([Fig. 1.9](#)). Some dermatopathologists insist on the presence of fibrin within the vessel wall before they will accept a diagnosis of vasculitis. This criterion is far too restrictive, and it ignores the fact that exudative features, such as fibrin extravasation, are not prominent in chronic inflammation in any tissue of the body. On the other hand, a diagnosis of vasculitis should not be made simply because there is a perivascular infiltrate of

inflammatory cells. Notwithstanding these comments, in resolving and late lesions of vasculitis there may only be a tight perivascular inflammatory cell infiltrate, making it difficult to make a diagnosis of vasculitis. Some of these cases may represent a cell-mediated attack on vessel walls. Endothelial cells, like epidermal Langerhans cells, are antigen processing cells and could evoke an inflammatory response. The presence of endothelial swelling in small vessels and an increase in fibrohistiocytic cells (a 'busy dermis') and sometimes acid mucopolysaccharides in the dermis are further clues that assist in confirming that a resolving vasculitis is present. Although it is useful to categorize vasculitis into acute, chronic lymphocytic, and granulomatous forms, it should be remembered that an acute vasculitis may progress with time to a chronic stage. Fibrin is rarely present in these late lesions.

Other categories of vascular disease include non-inflammatory purpuras, vascular occlusive diseases, and urticarias. The purpuras are characterized by extravasation of erythrocytes and the vascular occlusive diseases by fibrin and/or platelet thrombi or, rarely, other material in the lumen of small blood vessels. The urticarias are characterized by increased vascular permeability, with escape of edema fluid and some cells into the dermis. The neutrophilic dermatoses are included also because they share some morphological features with the acute vasculitides.

Figure 1.9 Acute vasculitis. Neutrophils are present in the wall of a vessel that also shows extravasation of fibrin. (H&E)

The diseases showing the vasculopathic reaction pattern are listed in [Table 1.6](#).

COMBINED REACTION PATTERNS

As mentioned previously, sometimes more than one of the major tissue reaction patterns is present in a particular disease, either as a feature of the evolution of the disease or as a characteristic feature of all stages of that condition. The combination of spongiotic and psoriasiform patterns is part of the evolution of many spongiotic diseases; it is not considered further.

The combinations most frequently encountered include lichenoid and spongiotic, lichenoid and granulomatous, and lichenoid and vasculopathic.

The various diseases that show these dual patterns are listed in [Table 1.7](#).

MINOR TISSUE REACTION PATTERNS

‘Minor tissue reaction patterns’ is a term of convenience for a group of reaction patterns in the skin that are seen much less frequently than the six major patterns already discussed. Like the major reaction patterns, each of the patterns to be considered here is diagnostic of a certain group of diseases of the skin. Sometimes, a knowledge of the clinical distribution of the lesions (e.g., whether they are localized, linear, zosteriform, or generalized) is required before a specific clinicopathological diagnosis can be made. The minor tissue reaction patterns to be discussed, with their key morphological feature in parentheses, are as follows:

1. *Epidermolytic hyperkeratosis* (hyperkeratosis with granular and vacuolar degeneration)
2. *Acantholytic dyskeratosis* (suprabasilar clefts with acantholytic and dyskeratotic cells)
3. *Cornoid lamellation* (a column of parakeratotic cells with absence of an underlying granular layer)
4. *Papillomatosis* – ‘church-spiring’ (undulations and protrusions of the epidermis)
5. *Angiofibromas* (increased dermal vessels with surrounding fibrosis)
6. *Eosinophilic cellulitis with ‘flame figures’* (dermal eosinophils and eosinophilic material adherent to collagen bundles)

Figure 1.10 Epidermolytic hyperkeratosis characterized by granular and vacuolar degeneration of the upper layers of the epidermis and overlying hyperkeratosis. (H&E)

7. *Transepithelial elimination* (elimination of material via the epidermis or hair follicles).

The first four patterns listed are all disorders of epidermal maturation and keratinization. They are discussed briefly here and in further detail in Chapter 9. Angiofibromas are included with tumors of fibrous tissue in Chapter 34, whereas eosinophilic cellulitis is discussed with the cutaneous infiltrates in Chapter 40. Transepithelial elimination is a process that may occur as a secondary event in a wide range of skin diseases. It is discussed later.

EPIDERMOLYTIC HYPERKERATOSIS

The features of the epidermolytic hyperkeratotic reaction pattern are *compact hyperkeratosis accompanied by granular and vacuolar degeneration of the cells of the spinous and granular layers* ([Fig. 1.10](#)). This pattern may occur in diseases or lesions that are generalized (bullous ichthyosiform erythroderma), systematized (epidermal nevus variant), palmar–plantar (a variant of palmoplantar keratoderma), solitary (epidermolytic acanthoma), multiple and discrete (disseminated epidermolytic acanthoma), or follicular (nevroid follicular hyperkeratosis). Rarely, this pattern may be seen in solar keratoses. Not uncommonly, epidermolytic hyperkeratosis is an incidental finding in a biopsy taken because of the presence of some other lesion.

ACANTHOLYTIC DYSKERATOSIS

Acantholytic dyskeratosis is characterized by *suprabasilar clefting with acantholytic and dyskeratotic cells at all levels of the epidermis* (see p. 302) ([Fig. 1.11](#)). It may be a generalized process (Darier’s disease), a systematized process (a variant of epidermal nevus), transient (Grover’s disease), palmar–plantar (a very rare form of keratoderma), solitary (warty dyskeratoma), an incidental finding, or a feature of a solar keratosis (acantholytic solar keratosis).

CORNOID LAMELLATION

Cornoid lamellation ([Fig. 1.12](#)) is localized faulty keratinization characterized by a thin column of parakeratotic cells with an absent or decreased underlying granular zone and vacuolated or dyskeratotic cells in the spinous layer (see p. 299). Although cornoid lamellation is

Table 1.6 Diseases showing the vasculopathic reaction pattern

Non-inflammatory purpuras	Sweet's syndrome
Traumatic purpura	Pustular vasculitis of the hands
Psychogenic purpura	Neutrophilic fixed drug eruption
Drug purpura	Bowel-associated dermatosis–arthritis syndrome
Bleeding diatheses	Rheumatoid neutrophilic dermatosis
Senile purpura	Acute generalized pustulosis
Vascular occlusive diseases	Behçet's disease
Protein C and protein S deficiencies	Abscess-forming neutrophilic dermatosis
Prothrombin gene mutations	Chronic lymphocytic vasculitis
Warfarin necrosis	Inherited lymphocytic vasculitis
Atrophie blanche (livedoid vasculopathy)	Toxic erythema
Disseminated intravascular coagulation	Collagen vascular disease
Purpura fulminans	PUPPP
Thrombotic thrombocytopenic purpura	Prurigo of pregnancy
Thrombocythemia	Gyrate and annular erythemas
Cryoglobulinemia	Pityriasis lichenoides
Cholesterol and other types of embolism	Pigmented purpuric dermatoses
Antiphospholipid syndrome	Malignant atrophic papulosis (Degos)
Factor V Leiden mutation	Perniosis
Sneddon's syndrome	Rickettsial and viral infections
CADASIL	Pyoderma gangrenosum
Miscellaneous conditions	Polymorphic light eruption (variant)
Urticarias	TRAPS
Acute vasculitis	Leukemic vasculitis
Leukocytoclastic (hypersensitivity) vasculitis	Vasculitis with granulomatosis
Henoch–Schönlein purpura	Crohn's disease
Eosinophilic vasculitis	Drug reactions
Rheumatoid vasculitis	Herpes zoster
Urticarial vasculitis	Infectious granulomatous diseases
Mixed cryoglobulinemia	Wegener's granulomatosis
Hypergammaglobulinemic purpura	Lymphomatoid granulomatosis (angiocentric lymphoma)
Hyperimmunoglobulinemia D syndrome	Churg–Strauss syndrome
Septic vasculitis	Lethal midline granuloma
Erythema elevatum diutinum	Giant cell (temporal) arteritis
Granuloma faciale	Takayasu's arteritis
Localized chronic fibrosing vasculitis	Miscellaneous vascular disorders
Microscopic polyangiitis (polyarteritis)	Vascular steal syndrome
Polyarteritis nodosa	Capillary leak syndrome
Kawasaki disease	Vascular calcification
Superficial thrombophlebitis	Pericapillary fibrin cuffs
Sclerosing lymphangitis of the penis	Vascular aneurysms
Miscellaneous associations	Erythermalgia
Neutrophilic dermatoses	Cutaneous necrosis and ulceration
Periodic fever syndromes	Paraneoplastic acral vascular syndrome
Amicrobial pustulosis of the folds	

Table 1.7 Diseases showing combined reaction patterns
Lichenoid and spongiotic
Lichen striatus
Spongiotic drug reactions
Morbilliform drug reactions (may also be vasculopathic)
Lichenoid contact dermatitis
Late-stage pityriasis rosea
Sulzberger–Garbe syndrome (oid-oid disease)
Nummular dermatitis
Superantigen ‘id’ reactions
DiGeorge syndrome
Gianotti–Crosti syndrome (may also be vasculopathic)
Eczematous GVHD
Lichenoid and granulomatous
Lichenoid sarcoidosis
Lichen nitidus
Lichen striatus (rare)
Secondary syphilis
Herpes zoster (late)
Tinea capitis
Mycobacterial infections
HIV infection
Drug reactions (often in setting of rheumatoid arthritis or Crohn’s disease – ACE inhibitors, antihistamines, atenolol, oxacillin, allopurinol, captopril, cimetidine, enalapril, erythropoietin, hydroxychloroquine, simvastatin, diclofenac, quinine, tetracycline, sulfa drugs)
Endocrinopathies
Hepatobiliary disease
Rheumatoid arthritis
Lichenoid and vasculopathic
Pityriasis lichenoides
Perniosis
Polymorphic light eruption (some cases)
Pigmented purpuric dermatoses (PPD)
Persistent viral reactions, particularly to herpes virus
Granulomatous and vasculopathic
Drug reactions (allopurinol, see lichenoid and granulomatous listings above)
Crohn’s disease
Granulomatous PPD
Granulomatous vasculitides
Spongiotic and vasculopathic
Rare reactions to viruses
Rare drug reactions

Hyperkeratosis lenticularis
Rubbed and scratched skin

a characteristic feature of porokeratosis and its clinical variants, it can be found as an incidental phenomenon in a range of inflammatory, hyperplastic, and neoplastic conditions of the skin.

PAPILLOMATOSIS ('CHURCH-SPIRING')

Papillomatosis refers to the presence of undulations or projections of the epidermal surface (Fig. 1.13). This may vary from tall 'steeple-like' projections to quite small, somewhat broader elevations of the epidermal surface. The term 'church-spiring' is sometimes used to refer to these changes. The various lesions showing papillomatosis are listed in Table 1.8.

ACRAL ANGIOFIBROMAS

The acral angiofibroma reaction pattern is characterized by an increase in the number of small vessels, which is associated with perivascular

Table 1.9 Conditions showing an angiofibromatous pattern

Adenoma sebaceum (tuberous sclerosis)
Angiofibromas in syndromes – MEN1, neurofibromatosis
Subungual and periungual fibroma
Acquired acral fibrokeratoma
Fibrous papule of the nose (and face)
Pearly penile papules
Familial myxovascular fibromas

and, sometimes, perifollicular fibrosis (see p. 968). The fibrous tissue usually contains stellate cells (Fig. 1.14). The conditions showing this reaction pattern are listed in Table 1.9.

EOSINOPHILIC CELLULITIS WITH 'FLAME FIGURES'

In eosinophilic cellulitis with 'flame figures', there is dermal edema with an infiltration of eosinophils and some histiocytes and scattered 'flame figures' (Fig. 1.15). 'Flame figures' result from the adherence of amorphous or granular eosinophilic material to collagen bundles in the dermis. They are small, poorly circumscribed foci of apparent 'necrobiosis' of collagen, although they are eosinophilic rather than basophilic as seen in the usual 'necrobiotic' disorders.

Eosinophilic cellulitis with 'flame figures' can occur as part of a generalized cutaneous process known as Wells' syndrome (see p. 1132). This reaction pattern, which may represent a severe urticarial hypersensitivity reaction to various stimuli, can also be seen, rarely, in biopsies from arthropod reactions, other parasitic infestations, internal cancers, bullous pemphigoid, dermatitis herpetiformis, diffuse erythemas, and *Trichophyton rubrum* infections. The 'flame figures' of eosinophilic cellulitis resemble the Splendore–Hoeppli deposits that are sometimes found around parasites in tissues.

TRANSEPITHELIAL ELIMINATION

The term 'transepithelial elimination' was coined by Mehregan for a biological phenomenon whereby materials foreign to the skin are eliminated through pores between cells of the epidermis or hair follicle or are carried up between cells as a passive phenomenon, during

Figure 1.15 Eosinophilic cellulitis with flame figures. (H&E)

Figure 1.16 Transepithelial elimination of solar elastotic material is occurring through an enlarged follicular infundibulum. (Verhoeff–van Gieson)

maturation of the epidermal cells.¹ The validity of this hypothesis has been confirmed using an animal model.² The process of transepithelial elimination can be recognized in tissue sections by the presence of pseudoepitheliomatous hyperplasia or expansion of hair follicles (Fig. 1.16). These downgrowths of the epidermis or follicle usually surround the material to be eliminated, and the term ‘epidermal vacuum cleaner’ can be applied to them. Various tissues, substances, or organisms can be eliminated from the dermis in this way, including elastic fibers, collagen, erythrocytes, amyloid, calcium salts, bone, foreign material, inflammatory cells and debris, fungi, and mucin.^{3–16} The various disorders (also known as ‘perforating disorders’) that may show transepithelial elimination are listed in Table 1.10.

An extension of this process is the **transdermal elimination** of fat. This occurs particularly after traumatic fat necrosis, but it rarely follows one of the panniculitides. Clinically, it presents as a ‘discharging’ lesion, but histologically, fat cells are often not found near the epidermis, suggesting that liquefied fat is involved in this discharge; it has presumably been removed during the processing of the specimen.

The apparent transepithelial elimination of a sebaceous gland has been reported.¹⁷ This process was probably an artifact of tissue sectioning.

Table 1.10 Diseases in which transepithelial elimination may occur
Necrobiosis lipoidica
Necrobiotic xanthogranuloma
Perforating folliculitis
Pseudoxanthoma elasticum
Elastosis perforans serpiginosa
Reactive perforating collagenosis
Calcaneal petechiae ('black heel')
Amyloidosis

Urate crystals
Calcinosis cutis
Osteoma cutis
Deep mycoses
Cutaneous tuberculosis
Blastomycosis-like pyoderma
Granuloma inguinale
Sarcoidosis
Foreign body granulomas
Exogenous pigment
Suture material
Lichen nitidus
Papular mucinosis
Acne keloidalis nuchae
Solar elastosis
Post-cryotherapy injury
Cutaneous tumors

PATTERNS OF INFLAMMATION

Four patterns of inflammation can be discerned in biopsies taken from the various inflammatory diseases of the skin: superficial perivascular inflammation, superficial and deep dermal inflammation, folliculitis and perifolliculitis, and panniculitis. Superficial band-like infiltrates are not included as a separate category because they are usually associated with the lichenoid reaction pattern (interface dermatitis) or the infiltrate is merely an extension of a superficial perivascular infiltrate.

SUPERFICIAL PERIVASCULAR INFLAMMATION

Superficial perivascular inflammation is usually associated with the spongiotic, psoriasiform, or lichenoid reaction patterns. Occasionally, diseases that are usually regarded as showing the spongiotic reaction pattern have only very mild spongiosis that may not always be evident on casual inspection of one level of a biopsy. This should be kept in mind when a superficial perivascular inflammatory reaction is present.

Causes of a superficial perivascular infiltrate, in the absence of spongiosis or another reaction pattern, include the following:

- Drug reactions
- Dermatophytoses
- Viral exanthems
- Chronic urticaria
- Erythrasma

Figure 1.17 There is a superficial and deep perivascular infiltrate of lymphocytes. The presence of mild lichenoid changes suggests a diagnosis of lupus erythematosus. (H&E)

- Superficial annular erythemas
- Pigmented purpuric dermatoses
- Resolving dermatoses.

SUPERFICIAL AND DEEP DERMAL INFLAMMATION

Superficial and deep dermal inflammation may accompany a major reaction pattern, as occurs in discoid lupus erythematosus, in which there is a concomitant lichenoid reaction pattern, and also in photo-contact allergic dermatitis, in which there is a spongiotic reaction pattern in addition to the dermal inflammation. This pattern of inflammation may also occur in the absence of any of the six major reaction patterns already discussed. The predominant cell type is usually the lymphocyte, but there may be a variable admixture of other cell types (**Fig. 1.17**). The often-quoted mnemonic of diseases causing this pattern of inflammation is the eight 'L' diseases – light reactions, lymphoma (including pseudolymphomas), leprosy, lues (syphilis), lichen striatus, lupus erythematosus, lipoidica (includes necrobiosis lipoidica and incomplete forms of granuloma annulare), and lepidoptera (used incorrectly in the mnemonic to refer to arthropod bites and other parasitic infestations). To the eight 'L' diseases should be added 'DRUGS' – drug reactions, as well as dermatophyte infections, reticular erythematous mucinosis, urticaria (chronic urticaria and the urticarial stages of bullous pemphigoid and herpes gestationis), gyrate erythemas (deep type), and scleroderma (particularly the localized variants).

This list is obviously incomplete, but it covers most of the important diseases having this pattern of inflammation. For example, the vasculitides and various granulomatous diseases have superficial and deep inflammation in the dermis, but they have been excluded from the mnemonics because they constitute major reaction patterns. It is always worth keeping in mind these mnemonics when a superficial and deep infiltrate is present in tissue sections.

FOLLICULITIS AND PERIFOLLICULITIS

Inflammation of the hair follicle (folliculitis) usually extends into the adjacent dermis, producing a perifolliculitis (**Fig. 1.18**). For this reason,

Figure 1.18 The acute folliculitis has ruptured with extension of the inflammatory infiltrate into the adjacent dermis. (H&E)

these two patterns of inflammation are considered together. There are several ways of classifying the various folliculitides, the most common being based on the anatomical level of the follicle (superficial or deep) that is involved. This distinction is not always clear-cut, and in some cases of folliculitis due to an infectious agent, the follicle may be inflamed throughout its entire length. The folliculitides are discussed in further detail in Chapter 15.

Infectious agents are an important cause of folliculitis and perifolliculitis, and diseases showing this pattern of inflammation are sometimes subclassified into 'infective' and 'non-infective' groups. If this etiological classification is used in conjunction with the anatomical level of the follicle most affected by the inflammation, four groups of folliculitides are produced. The important diseases in each of these groups are listed in parentheses:

1. *Superficial infective folliculitis* (impetigo, some fungal infections, herpes simplex folliculitis, and folliculitis of secondary syphilis)
2. *Superficial non-infective folliculitis* (infundibulofolliculitis, actinic folliculitis, acne vulgaris (?), acne necrotica, and eosinophilic pustular folliculitis)
3. *Deep infective folliculitis* (kerion, favus, pityrosporum folliculitis, Majocchi's granuloma, folliculitis decalvans, furuncle, and herpes simplex folliculitis)
4. *Deep non-infective folliculitis* (hidradenitis suppurativa, dissecting cellulitis of the scalp, acne conglobata, and perforating folliculitis).

In sections stained with H&E, the division into superficial or deep folliculitis can usually be made, except in cases with overlap features. Further subdivision into infective and non-infective types may require the use of special stains for organisms. It should be remembered that the involved hair follicle may not be present in a particular histological section, and serial sections may need to be studied. An apparent 'uneven vasculitis' (involving a localized part of the biopsy) is a clue to the presence of a folliculitis in a deeper plane of section.

PANNICULITIS

Inflammatory lesions of the subcutaneous fat can be divided into three distinct categories: *septal panniculitis*, in which the inflammation is confined to the interlobular septa of the subcutis; *lobular panniculitis*, in which the inflammation involves the entire fat lobule and often the

Figure 1.19 (A) A panniculitis of lobular type is present in a case of pancreatic panniculitis. (B) Another example of a lobular panniculitis in a patient with erythema induratum–nodular vasculitis. (H&E)

Parakeratosis as a helpful sign	25	Clues to mycosis fungoides	30	False-negative immunoperoxidase	33
Parakeratotic follicular lipping	25	Clues to alopecia areata	30	Miscellaneous hints	33
		Clues to androgenetic alopecia	30		

In the previous chapter, an orderly approach to the diagnosis of inflammatory skin lesions was discussed. This chapter records in list form some useful points that may assist in reaching a correct diagnosis. Many of the clues that follow produce diagnostic lists that are not necessarily related to tissue reaction, etiology, or pathogenesis.

Some of the clues that follow are original observations; many have been around for decades. An acknowledgment should be made here of the work of Bernard Ackerman, who has contributed more 'clues' to diagnostic dermatopathology than anyone else.

Like all 'shortcuts', the following 'clues' must be used with caution. They are not absolute criteria for diagnosis, and they are not invariably present at all stages of a disease. An attempt has been made to group the clues into several sections.

FEATURES OF PARTICULAR PROCESSES

SIGNS OF PHOTOSENSITIVITY (Fig. 2.1)

- Dilated vessels in the upper dermis
- Stellate fibroblasts/dendrocytes
- Deep elastotic fibers
- Deep extension of the infiltrate
- Epidermal 'sunburn' cells.

Note: The duration of the process and the underlying nature of the light reaction will influence the response. Only one or two features may be present, for example, sunburn cells (apoptotic keratinocytes) are confined to phototoxic and photosensitive drug eruptions.

SIGNS OF RUBBING/SCRATCHING (Fig. 2.2)

<i>Acute, severe:</i>	Pale pink epidermis, sometimes with loss of cell borders; pinpoint erosions or larger ulcers; fibrin below the epidermis
<i>Chronic, persistent:</i>	Psoriasiform epidermal hyperplasia; vertical streaks of collagen in the papillary dermis; stellate fibroblasts/dendrocytes; fibroplasia of varying amounts; enlarged follicular infundibula (as prurigo nodularis commences); compact orthokeratosis.

SUBTLE CLUES TO DRUG REACTIONS

- Superficial dermal edema
- Activated lymphocytes
- Eosinophils and/or plasma cells
- Red cell extravasation
- Endothelial swelling of vessels
- Exocytosis of lymphocytes
- Apoptotic keratinocytes.

The changes present will mirror the clinical types of reaction. In morbilliform reactions, lymphocytes extend into the lower epidermis and the apoptotic keratinocytes are in the basal layer.

CLUES TO ELASTIC TISSUE ALTERATIONS

- Small blue coiled/clumped fibers (pseudoxanthoma elasticum)
- Wavy epidermis (particularly in children)
- Elastophagocytosis
- Dispersed neutrophils (early cutis laxa)
- Unusually thickened collagen (connective tissue nevus).

Figure 2.1 Photosensitivity reaction. (A) Note the mild telangiectasia, scattered stellate cells, deep extension of the infiltrate, and mild deep solar elastosis. (B) Note the stellate cells. (H&E)

Figure 2.2 Chronic rubbing leading to vertical collagen in the papillary dermis and psoriasiform hyperplasia of the epidermis. (H&E)

CLUES TO DEFICIENCY STATES

- Confluent parakeratosis
- Superficial epidermal necrosis and/or pallor
- Mild psoriasiform hyperplasia
- Hemorrhage (in pellagra and mixed deficiencies).

CLUES TO FUNGAL INFECTIONS (Fig. 2.3)

Basically, these features should prompt the performance of a PAS stain. Many simulants exist.

- Compact orthokeratosis with no other explanation
- Layering of epidermal cornification ('sandwich sign')
- Neutrophils in the epidermis/stratum corneum
- Spongiosis, particularly palmoplantar
- Suppurative folliculitis.

Figure 2.3 Dermatophyte. The fungal elements are present in the region with compact orthokeratosis. Note the adjacent normal 'basket-weave' pattern. (H&E)

SUBTLE CLUES TO A FOLLICULITIS (Fig. 2.4)

These signs refer to a likely folliculitis at deeper levels of the biopsy.

- Neutrophils on top of the stratum corneum
- Neutrophils at the edge of the tissue section
- Uneven vasculitis (centered in one small area) – miliaria may do the same
- Focal splaying of neutrophils and dust in mid dermis.

'LAST WEEK'S SIGN' (Fig. 2.5)

This refers to a dermatosis, no longer active, that is 'playing itself out'. It was presumably more active some days earlier.

- Parakeratosis overlying basket-weave orthokeratin (the key feature)
- Mild hyperplasia of the epidermis
- Mild dermal inflammation.

LAGGING HISTOLOGY

This refers to several conditions in which the clinical appearances may be striking in comparison to the histology.

- Sclerodermoid GVHD may have 'rock-hard skin' but only subtle collagen deposition
- Cicatricial alopecia can be similar
- Urticaria: Histology underestimates the edema because of dehydration during tissue processing
- Prurigo nodularis: There may be clinical nodules but no histological swollen infundibula, only psoriasiform hyperplasia of lichen simplex chronicus
- Pauci-cellular photodermatoses: There may be striking clinical changes but only telangiectasia and sparse inflammatory cells on histology.

Figure 2.4 Folliculitis. There is deep dermal inflammation and an 'uneven vasculitis' more superficially. A ruptured and inflamed follicle was present on deeper levels. (H&E)

HISTOLOGICAL FEATURES – WHAT DO THEY SUGGEST?

SUPERFICIAL AND DEEP INFLAMMATION (Fig. 2.6)

The presence of a superficial and deep inflammatory cell infiltrate within the dermis should trigger the mnemonic '8Ls + DRUGS'.

8Ls

- Light reactions
- Lymphoma
- Leprosy
- Lues
- Lichen striatus
- Lupus erythematosus
- Lipoidica (necrobiosis)
- Lepidoptera (and other arthropods)

Drugs

- Dermatophyte
- Reticular erythematous mucinosis
- Urticarial stages (bullous pemphigoid)
- Gyrate erythemas
- Scleroderma (localized)
- And, of course, drug reactions

Figure 2.5 'Last week's sign'. The return to the production of normal basket-weave keratin beneath a layer of parakeratosis suggests there is little ongoing activity in this region. (H&E)

Figure 2.6 A superficial and deep dermal infiltrate. This is one of the 'L' diseases – polymorphic light eruption. (H&E)

Figure 2.7 A 'busy' dermis. There is hypercellularity in this case of interstitial granulomatous drug reaction. (H&E)

A 'BUSY' DERMIS (Fig. 2.7)

'Busy' refers to a dermis that appears focally hypercellular on scanning magnification and is not usually due to the usual inflammatory infiltrates.

- Incomplete form of granuloma annulare
- Interstitial granulomatous dermatitis
- Interstitial granulomatous drug reaction
- Resolving vasculitis (increased mucin also)
- Chronic photodermatoses
- Folliculitis – at deeper levels (cells are neutrophils and dust)
- Subtle breast carcinoma recurrence
- Desmoplastic melanoma (also perivascular lymphocytes)
- Kaposi's sarcoma (early stage).

ABSENT STRATUM CORNEUM

- Staphylococcal scalded skin syndrome
- Pemphigus foliaceus
- Peeling skin syndrome
- Psoriatic erythroderma (psoriasiform hyperplasia present)
- Artifacts.

FILLED PAPILLARY DERMIS (Fig. 2.8)

The low power impression is that of a variably hypercellular papillary dermis. Excluded from consideration are nodular and diffuse infiltrates also involving the reticular dermis. The 'LUMP' mnemonic covers most cases: *lichenoid*, *urticaria pigmentosa*, *mycosis fungoides*, *pigmented purpuric dermatoses*. Expressed differently they are as follows:

- Most of the lichenoid tissue reactions
- Pigmented purpuric dermatoses
- Cutaneous T-cell lymphoma
- Parapsoriasis (if not included above)
- Some mastocytomas
- Early lichen sclerosis et atrophicus.

Figure 2.8 The papillary dermis is filled. This is mastocytosis. (H&E)

Figure 2.9 Dermal papillary microabscess. This is dermatitis herpetiformis. (H&E)

PAPILLARY MICROABSCESSES (Fig. 2.9)

- Dermatitis herpetiformis
- Linear IgA disease
- Cicatricial pemphigoid
- Localized cicatricial pemphigoid
- Bullous lupus erythematosus
- Epidermolysis bullosa acquisita
- Drugs
- Hypersensitivity vasculitis (rare)
- Rheumatoid neutrophilic dermatosis
- Pemphigoid gestationis (eosinophils)
- Deep lamina lucida pemphigoid
- Generalized exanthematous pustulosis (rare).

SPARSE PERIVASCULAR NEUTROPHILS

In some conditions, neutrophils are relatively sparse or less conspicuous than in vasculitis, a neutrophilic dermatosis or cellulitis.

Figure 2.10 Thickened basement membrane and mild basal vacuolar change. This is an example of systemic lupus erythematosus. (H&E)

- Erythema marginatum
- Still's disease
- Neutrophilic urticaria
- Mild periodic fever syndromes
- Early or subsiding neutrophilic dermatoses
- Neutrophilic erythemas of infancy
- Some flea bites.

THICKENED BASEMENT MEMBRANE (Fig. 2.10)

- Lupus erythematosus
- Dermatomyositis (less so)
- Lichen sclerosus et atrophicus.

MID-DERMAL INFILTRATE AND MUCIN (Fig. 2.11)

- Cutaneous lupus erythematosus
- Reticular erythematous mucinosis (REM)
- Jessner's lymphocytic infiltrate.

Other signs will usually allow these diagnoses, but sometimes REM will present with very little deep infiltrate. Biopsies appear to have a 'mid-dermal plexus'. Dermatomyositis can have mucin, but the infiltrate is only superficial. Perifollicular mucin can be seen in Carney's complex. REM and Jessner's infiltrate (no longer used) are both patterns of expression of cutaneous lupus erythematosus.

EPIDERMOTROPISM AND EXOCYTOSIS (Fig. 2.12)

The terms 'epidermotropism' and 'exocytosis' are often used interchangeably. It is best to restrict them as follows:

Exocytosis:

Random emigration of inflammatory cells through the epidermis; some cells will reach the surface. It is common in inflammatory dermatoses. In the spongiotic tissue reaction, it may be a striking feature in nummular dermatitis and spongiotic drug reactions

Figure 2.11 A 'mid-dermal plexus' with perivascular inflammation is present. Lupus and reticular erythematous mucinosis (REM) can do this (they may be the one condition). The mucin is difficult to appreciate. (H&E)

Figure 2.12 Epidermotropism. The cells are confined to the lower one-third to one-half of the epidermis. (H&E)

Figure 2.13 Epidermal 'vacuum cleaner'. The acanthotic downgrowth serves as a site for transepidermal elimination of elastotic material in this case of perforating pseudoxanthoma elasticum. (H&E)

Epidermotropism: Refers to directed emigration of lymphocytes; it usually involves only the lower one-third to half of the epidermis. The cells have a tendency to aggregate. There is little, if any, accompanying spongiosis. It is a feature of mycosis fungoides.

THE EPIDERMAL/FOLLICULAR 'VACUUM CLEANER' (Fig. 2.13)

The epidermal/follicular 'vacuum cleaner' is the author's term for the irregular epidermal hyperplasia ± enlarged follicular infundibula, associated with the transepidermal elimination of material from the dermis. It can be subtle following cryotherapy to sun-damaged skin; it may be the cause of a persistent lesion at the site, often mistaken as a clinical recurrence.

PARAKERATOSIS AS A HELPFUL SIGN

<i>Lipping:</i>	See below
<i>Spongiosis:</i>	Pityriasis rosea, erythema annulare centrifugum, seborrheic dermatitis, other spongiotic diseases
<i>Neutrophils:</i>	Psoriasis (neutrophils in 'summits' of mounds), seborrheic dermatitis, dermatophyte infection, necrolytic erythema, secondary bacterial infection
<i>In tiers:</i>	Parakeratosis, verruca vulgaris, palmoplantar psoriasis
<i>With interface change:</i>	Lichenoid drug, lichen planus-like keratosis, pityriasis lichenoides, lupus erythematosus (more often orthokeratosis)
<i>Overlying orthokeratosis:</i>	Healing lesion or intermittent activity, particularly a spongiotic process
<i>Alternating:</i>	Alternating orthokeratosis and parakeratosis in a horizontal direction is seen in ILVEN, and actinic keratosis, and

Figure 2.14 'Chunks of coal'. Cells with large, dark, hyperchromatic nuclei are present in the dermis in this case of lymphomatoid papulosis. (H&E)

Broad thick zones: in a horizontal and vertical direction in pityriasis rubra pilaris
Psoriasis, glucagonoma and deficiency states (epidermal pallor is not invariable), pityriasis lichenoides, granular parakeratosis.

PARAKERATOTIC FOLLICULAR LIPPING

- Seborrheic dermatitis
- Pityriasis rubra pilaris (follicular lesions)
- Spongiotic processes, or psoriasis, on the face. The large number of follicles on the face means that they are more likely to be involved incidentally in any condition with parakeratosis.

'CHUNKS OF COAL' (Fig. 2.14)

Large atypical lymphoid cells within a heavy mixed infiltrate occur in lymphomatoid papulosis. The cells have been likened to 'chunks of coal'.

Figure 2.15 Interstitial eosinophils in an insect bite reaction. (H&E)

INTERSTITIAL EOSINOPHILS (Fig. 2.15)

'Interstitial eosinophils' refers to the presence of eosinophils between collagen bundles and away from vessels. Perivascular eosinophils are also present.

- Arthropod bites
- Cnidarian contact
- Other parasite infestations
- Drug reactions
- Toxic erythema of pregnancy
- Annular erythemas of infancy
- Wells' syndrome
- Dermal hypersensitivity
- Hypereosinophilic syndrome
- Urticaria
- Urticarial stages of bullous pemphigoid, pemphigoid gestationis
- Internal malignancy (rare).

Large numbers of eosinophils in suspected bite reactions suggest scabies or a hypersensitive state to the arthropod. Prebullous pemphigoid also has numerous eosinophils.

'BOTTOM-HEAVY' INFILTRATES

Dense lymphoid infiltrates may be found in the lower dermis in the following circumstances:

- Cutaneous lymphoma
- Herpes folliculitis
- Hidradenitis suppurativa (mixed infiltrate + scarring).

THE 'BARE UNDERBELLY' SIGN (Fig. 2.16)

In some cases of mycosis fungoides, the lymphocytes are present on the upper (epidermal) side of the superficial vascular plexus with few, if any, on the undersurface. This is possibly a reflection of their directed migration to the epidermis. It is an unreliable sign, but a striking one in some cases.

Figure 2.16 The 'bare underbelly' sign. Note the paucity of lymphocytes on the undersurface of the superficial vascular plexus. (H&E)

Figure 2.17 An intraluminal giant cell. The patient had chronic infections of the genital and inguinal region. (H&E)

INTRALUMINAL GIANT CELLS/HISTIOCYTES (Fig. 2.17)

- Melkersson–Rosenthal syndrome
- Recurrent genitocrural infections
- Cutaneous histiocytic lymphangitis (angioendotheliomatosis)
- Rosai–Dorfman disease.

INTRAVASCULAR LEUKOCYTES

Leukocytes (eosinophils and/or neutrophils) are often present in the lumen of small vessels in the upper dermis in urticaria, even in the absence of accompanying vasculitis, and in lymphomatoid papulosis.

HIGH APOPTOTIC (DYSKERATOTIC) KERATINOCYTES (Fig. 2.18)

Presumptive apoptotic keratinocytes (the author has not stained them or examined them ultrastructurally in most entities listed) may occur in the spinous layer in the following:

Figure 2.18 High apoptotic keratinocytes in a drug reaction. (H&E)

- Lichenoid tissue reaction – true ‘interface-obscuring’ subtype
- Drug reactions
- Light reactions
- Resolving viral and putative viral lesions
- AIDS-related seborrheic dermatitis
- Incontinentia pigmenti (second stage)
- Tumors (e.g., Bowen’s disease)
- Rarely in normal skin and other inexplicable circumstances
- Near an excoriation
- Glucagonoma syndrome
- Acrodermatitis enteropathica
- Bazex’s syndrome.

VERTICAL COLLAGEN BUNDLES

Vertically oriented collagen bundles in the *reticular* dermis (usually combined with other bundles in random array) are seen in the following:

- Collagenous and elastotic plaques of the hand
- Digital fibromatosis of childhood
- Acral fibrokeratomas.

LOOSE PINK FIBRILLARY COLLAGEN (Fig. 2.19)

If such tissue is surrounded by a granulomatous rim with foreign body giant cells, this is probably tophaceous gout in which the crystals have dissolved out in aqueous solutions.

EXTRAVASATED ERYTHROCYTES

- Vasculitides of all types
- Pigmented purpuric eruptions (included above)
- Certain drug eruptions
- Some viral, rickettsial infections, septicemia and erysipelas
- Some arthropod reactions
- Pityriasis rosea (often into basal epidermis)
- Bleeding diatheses – purpura, DIC
- Scurvy
- Kaposi’s sarcoma

Figure 2.19 Giant cells surround eosinophilic material in this tophaceous gout that was fixed in formalin, dissolving out the urate crystals. (H&E)

Figure 2.20 Pale cells are present in the upper epidermis in this case of glucagonoma syndrome. (H&E)

- Lichen sclerosus et atrophicus
- Biopsy trauma
- Trichotillomania
- Stasis dermatitis
- Porphyria cutanea tarda (in blister)
- Discoid lupus erythematosus.

PALLOR OF EPIDERMAL CELLS (Fig. 2.20)

- Pellagra
- Acrodermatitis enteropathica
- Glucagonoma syndrome
- Hartnup disease
- Deficiency of M-subunit, lactate dehydrogenase
- Acroerythema
- Spongiotic diseases (variable)
- Clear cell acanthoma
- Clear (pale) cell acanthosis

- Clear cell papulosis
- Pagetoid dyskeratosis
- Colloid keratosis.

Note: This list could include other conditions, but they are usually diagnosed by other clues (e.g., lichen planus, pityriasis lichenoides chronica, and orf).

CLEAR CELL TUMORS

Epidermal-derived

- Clear cell acanthoma
- Bowen's disease
- Basal cell carcinoma
- Squamous cell carcinoma.

Adnexal tumors

- Paget's disease
- Clear cell syringoma
- Clear cell syringofibroadenoma
- Clear cell dermal duct tumor
- Clear cell hidradenoma (apocrine hidradenoma)
- Clear cell hidradenocarcinoma (apocrine hidradenocarcinoma)
- Clear cell eccrine carcinoma
- Clear cell porocarcinoma
- Clear cell myoepithelioma
- Clear cell trichoblastoma
- Tricholemmoma
- Trichilemmal carcinoma
- Sebaceous adenoma
- Sebaceous carcinoma
- Adnexal clear cell carcinoma with comedonecrosis.

Nevomelanocytic

- Balloon cell nevus
- Balloon cell melanoma
- Clear cell melanoma
- Clear cell sarcoma.

Mesenchymal

- Clear cell dermatofibroma
- Clear cell atypical fibroxanthoma
- Clear cell fibrous papule
- Clear cell leiomyoma
- Dermal clear cell mesenchymal tumor
- Neurofibroma (focal)
- Hemangioblastoma
- Malignant glomus tumor.

Histiocytoses

- Papular xanthoma
- Xanthoma disseminatum
- Tuberous xanthoma
- Verruciform xanthoma
- Necrobiotic xanthogranuloma.

Salivary gland

- Acinic cell carcinoma
- Hyalinizing clear cell carcinoma
- Clear cell mucoepidermoid carcinoma.

Metastases

- Renal cell carcinoma
- Breast carcinoma
- Hepatocellular carcinoma
- Pulmonary adenocarcinoma and mesothelioma.

GRANULAR CELL TUMORS

- Granular cell tumor
- Congenital gingival granular cell tumor
- Primitive non-neural (polypoid) granular cell tumor
- Neurofibroma
- Perineurioma
- Neuroendocrine adenoma
- Dermatofibroma
- Epithelioid cell histiocytoma
- Dermatofibrosarcoma protuberans
- Atypical fibroxanthoma
- Fibrous papule
- Basal cell carcinoma
- Ameloblastoma
- Angiosarcoma
- Melanocytic tumors (compound nevus, melanoma)
- Myogenic tumors (leiomyoma, leiomyosarcoma)
- Hibernoma
- Adnexal tumors
- Paraganglioma.

PLEXIFORM TUMORS

Melanocytic

- Spitz nevus
- Spindle cell nevus
- Deep penetrating nevus
- Cellular blue nevus
- Congenital nevus
- Malignant melanoma, particularly spindle-cell variant
- Melanocytoneuroma.

Neural

- Neurofibroma
- Pigmented plexiform neurofibroma
- Neurilemmoma, including epithelioid variant
- Neurothekeoma
- Perineurioma
- Plexiform granular cell tumor.

Mesenchymal

- Dermatofibroma
- Atypical fibroxanthoma

Figure 2.21 A Touton-like giant cell with hemosiderin-containing lipid layer in dermatofibroma. (H&E)

- Plexiform fibrohistiocytic tumor
- Fibrous hamartoma of infancy
- Leiomyoma (focal only)
- Ossifying plexiform tumor.

Miscellaneous

- Plexiform xanthoma
- Plexiform xanthomatous tumor.

TUMORS WITH HEMOSIDERIN (Fig. 2.21)

- Many vascular tumors (particularly Kaposi's sarcoma and angiosarcoma)
- Dermatofibroma (common)
- Dermatofibrosarcoma protuberans (rare)
- Atypical fibroxanthoma
- Giant cell tumor
- Melanoma
- Pleomorphic hyalinizing angiectatic tumor
- Hemosiderotic fibrohistiocytic lipomatous tumor
- Plexiform fibrohistiocytic tumor
- Epithelioid sarcoma
- Neurilemmoma.

Dermatofibromas, especially 'histiocytic', lipidized, and aneurysmal types, often contain a particular type of giant cell that resembles a Touton giant cell, with a central core of eosinophilic cytoplasm, multiple peripheral nuclei, and a surrounding lipid layer. These giant cells often have elongated or angulated contours. In addition, the nuclei appear to protrude into the lipid layer, in which hemosiderin granules are identified. This cell type is almost pathognomonic for dermatofibroma and can often help make the diagnosis even in a partial or poorly oriented biopsy specimen.

CLUES TO A PARTICULAR DISEASE

CLUES TO HERPES FOLLICULITIS (Fig. 2.22)

- Bottom-heavy infiltrate
- Sebaceitis

Figure 2.22 'Sebaceitis' in a case of herpes folliculitis. (H&E)

- Lichenoid changes around follicle ± epidermis
- Necrotic lower follicle
- Multinucleate epithelial cells, on searching.

CLUES TO GROVER'S DISEASE

- Focal acantholytic dyskeratosis with spongiosis
- Late lesions have elongated rete ridges and may resemble an early solar keratosis
- Eosinophils and less thick parakeratotic plugs may distinguish it from Darier's disease. The Darier variant may have a thick plug.

CLUES TO PITYRIASIS RUBRA PILARIS

- Most early cases are easily missed
- Alternating orthokeratosis and parakeratosis takes at least 14 days (probably longer) to develop
- Acantholytic dyskeratosis may be a clue; it is unfortunately uncommon (perhaps 1 in 20 biopsies).

CLUES TO CICATRICAL PEMPHIGOID

- Subcutaneous blister with neutrophils
- Split may extend down follicles
- Dermal fibrosis (detected early by the presence of parallel collagen, on polarization)
- Extruded sebaceous gland within the blister.

Remember that even early lesions may show dermal fibrosis because blisters tend to recur at the site of a previous one.

CLUES TO EPIDERMOLYSIS BULLOSA ACQUISITA

- Antibodies deposit in the dermal floor in salt-split skin
- U-serrated immunodeposition pattern.

There are three patterns of linear fluorescence at the basement membrane zone: true linear, n-serrated, and u-serrated. The u-serrated pattern differentiates type VII targeting diseases (epidermolysis bullosa acquisita and bullous lupus erythematosus) from other subepidermal bullous autoimmune diseases (see p. 164).

Figure 2.23 Mycosis fungoides. Note the epidermotropism and haloed lymphocytes within the epidermis. (H&E)

CLUES TO MYCOSIS FUNGOIDES (Fig. 2.23)

- Pautrier's microabscesses (only present in one-third)
- Haloed lymphocytes
- Epidermotropism without spongiosis
- Lymphocytes aligned within the basal layer
- Hyperconvoluted intraepidermal lymphocytes
- Epidermal lymphocytes larger than dermal ones
- Filling of the papillary dermis
- The 'bare underbelly' sign (unreliable)
- Fibrotic, thickened papillary dermis.

CLUES TO ALOPECIA AREATA

- Virtually all terminal follicles in the same stage
- 'Swarm of bees' (lymphocytes) in the hair bulb
- Increased catagen/telogen at advancing edge
- Presence of nanogen follicles.

CLUES TO ANDROGENETIC ALOPECIA

- Progressive decrease in follicular size
- Increase in vellus follicles
- Follicles do not extend into subcutis
- Increase in telogen hairs.

LATE BULLOUS LESIONS

- | | |
|----------------------------------|--|
| <i>Dermatitis herpetiformis:</i> | Intracorneal nuclear dust aggregates |
| <i>Pemphigus foliaceus:</i> | Dyskeratotic cells with hyperchromatic nuclei in granular layer. |

GRANULOMA ANNULARE VERSUS NECROBIOSIS LIPOIDICA

- | | |
|-------------------------------|---|
| <i>Necrobiosis lipoidica:</i> | Likened to 'stacks of plates' with multilayered necrobiosis and 'open ends'; thickened collagen bundles may be seen within palisaded granulomas. Numerous plasma cells favor this diagnosis |
| <i>Granuloma annulare:</i> | Usually not multilayered and open ended, but palisading continues around the edges of the palisading granulomas; central acid mucopolysaccharides; plasma cells uncommon. |

GRANULOMA ANNULARE VERSUS LICHEN NITIDUS

In disseminated granuloma annulare, small, poorly formed granulomas may develop in the upper dermis, sometimes mimicking lichen nitidus. Granuloma annulare does not usually have claw-like acanthotic downgrowths at the edge; it often has focal 'necrobiosis' (collagenolysis).

CLUES TO TRICHOEPITHELIOMA (OVER BCC)

- Papillary mesenchymal bodies ('stromal induction')
- CD34⁺ stromal cells around the island
- No clefts around the nests
- Presence of CD20⁺ Merkel cells
- Ruptured keratinous cysts
- Only basal layer *bcl-2* expression
- A central dell/depression in the skin surface.

CLUE TO ANGIOSARCOMA

- A positive head-tilt maneuver.

If an angiosarcoma of the head or neck is present, placing the head below the level of the heart results in the area of involvement becoming more violaceous and engorged (see p. 1108).

CLUES TO KAPOSI'S SARCOMA

- Abnormal tissue spaces in the dermis
- Promontory sign (small vessel protruding into an abnormal space)
- Hemosiderin and plasma cells

Figure 2.24 Cutaneous amyloidosis. Dendritic melanophages within hyaline deposits in the papillary dermis. (H&E)

- Stuffing of all dilated neoplastic vessels with erythrocytes in the absence of plasma
- Established lesions have the usually documented features.

CLUES TO BACILLARY ANGIOMATOSIS

Pyogenic granuloma-like lesion with nuclear dust and clumps of purplish material.

CLUES TO AMYLOIDOSIS (Fig. 2.24)

- Pale pink hyaline material in the papillary dermis
- Dendritic melanophages are present in some deposits. They are 'diagnostic'.

PARANEOPLASTIC DERMATOSES

In a useful review, Chung *et al.* (J Am Acad Dermatol 2006;54:745–762) listed 16 of the best-established paraneoplastic dermatoses that display distinctive clinical and pathological features. They are the following:

- Acanthosis nigricans
- Acquired ichthyosis
- Bazex's syndrome
- Cutaneous amyloidosis
- Dermatomyositis
- Erythema gyratum repens
- Hypertrichosis lanuginosa acquisita
- Leser-Trélat sign
- Multicentric reticulohistiocytosis
- Necrobiotic xanthogranuloma
- Necrolytic migratory erythema
- Paraneoplastic pemphigus
- Pyoderma gangrenosum
- Scleromyxedema

Figure 2.25 Epidermal nevus with flat-topped papillomatosis – the 'mesa' sign. (H&E)

- Sweet's syndrome
- Tripe palms.

Granuloma annulare could also have been added.

CLUE TO EPIDERMAL NEVI – THE 'MESA' SIGN (Fig. 2.25)

A helpful clue to the diagnosis of epidermal nevus is the 'mesa sign'. The tips of epidermal papillations are often flattened in epidermal nevi, resembling the flat-topped hill with steep sides that characterizes this geological formation. Papillomatous tips tend to be rounded or pointed in other, similar-appearing lesions, such as verrucae and seborrheic keratoses.

GENERAL HELPFUL HINTS AND CAUTIONS

NEARLY NORMAL SKIN (Fig. 2.26)

A number of cutaneous lesions, including some that may have striking clinical findings, show minimal discernible abnormalities in routine H&E-stained sections, especially at low magnification. These have also been called 'invisible dermatoses' or 'nothing lesions'. Diagnosis in such cases requires accurate clinical information, special staining for organisms or connective tissue changes, or occasionally ultrastructural study (e.g., in the case of depigmented or hypopigmented disorders). The following is a list of disorders that give the impression of nearly normal skin:

- Pityriasis alba
- Tinea versicolor
- Dermatophytosis
- Pitted keratolysis
- Urticaria
- Telangiectasia macularis eruptiva perstans
- Macular amyloidosis
- Solar elastosis
- Anetoderma

Figure 2.26 Nearly normal skin. These are examples of lesions in which histopathologic changes on H&E stained sections are minimal. (A) Vitiligo; (B) acquired ichthyosis. (H&E)

- Papillary and mid-dermal elastolysis
- Cutis laxa
- Connective tissue nevus
- Miliaria crystallina
- Hyperpigmented disorders
- Hypopigmented disorders
- Ichthyosis vulgaris, acquired ichthyosis
- Anhidrotic ectodermal dysplasia
- Dermal melanocytosis
- Nevus flammeus.

BEWARE OF KERATOACANTHOMA SIMULANTS

- Clinically, squamous cell carcinomas may grow quickly in the very elderly, simulating a keratoacanthoma. Squamous cell carcinoma may arise in a keratoacanthoma; this is very common in patients older than age 85 years

Figure 2.27 Equine fungus that is demonstrable only with silver stains. (Silver methenamine)

- Squamous cell carcinomas overlying rigid structures (e.g., cartilage of ear, base of nose, or bone of the tibia) may have infolding of margins simulating the architecture of a keratoacanthoma
- Keratoacanthomas have a unique pattern of cell differentiation (pink cytoplasm and large central cells).

BE CAUTIOUS WITH AMYLOID STAINS

- In solar elastotic skin, false-positive staining may occur with Congo red because differentiation may not remove all the stain from elastotic collagen
- A progressive stain (alkaline Congo red) may be better in these circumstances
- False-negative reactions may occur with the Congo red stain in macular amyloidosis
- The crystal violet stain is the most useful stain for amyloid keratin.

‘UP IT HALF A GRADE’

The author still remembers the advice given to him by Malcolm B. Dockerty, MD, at the Mayo Clinic more than 35 years ago.

- If it is a lesion on the lip, ‘up it half a grade’
- If it is a conjunctival nevus, ‘down it half a grade’.

‘DO SERIALS, NOT DEEPERS’

If suppurative granulomas are present, a fungal element (e.g., asteroid body in sporotrichosis) is usually present in each granuloma. Serial sections will ensure that the entire focus is sampled. Random deeper levels may miss the organism.

FUNGI MAY BE MISSED ON PAS STAIN (Fig. 2.27)

- ‘Dead’ fungi do not always stain with the PAS method
- The equine fungus *Phythrion* does not stain.

The silver methenamine method will stain the fungi in both cases, but it is not always reliable with the zygomycoses.

Figure 2.28 Pretibial pruritic papular dermatitis (PPPD). This neglected entity has a widened papillary dermis with stellate cells. It has a vague scanning power resemblance (apart from the expanded papillary dermis) to pigmented purpuric dermatosis (PPD). (H&E)

DERMAL NEUTROPHILS – OFTEN FORGOTTEN

Dermal and/or subcutaneous neutrophils may be seen in numerous conditions. They are discussed in Chapter 40. The author has temporarily ‘missed’ some of the following conditions through failure to think of them:

- Infections
- Acute cutis laxa
- α_1 -Antitrypsin deficiency
- Eruptive xanthoma (extracellular lipid may assist)
- Folliculitis on deeper levels
- Excoriation on deeper levels
- Neutrophilic urticaria
- Erythema nodosum leprosum
- Dermatomyositis
- Polymorphic light eruption.

See Chapter 40 (Table 40.1) for a complete list.

ITCHING ANKLES (Fig. 2.28)

There are many causes of pruritus of the lower pretibial region, only some of which are listed here. The conditions listed include several that can be fully characterized by special stains or supporting clinical history:

- Lichen planus/hypertrophic lichen planus
- Lichen simplex chronicus
- Lichen amyloidosis
- Arthropod bites
- Itching purpura
- Pretibial pruritic papular dermatitis (see p. 96).

Clinically, pretibial pruritic papular dermatitis resembles lichen simplex chronicus or lichen amyloidosis; pathologically, it resembles

Figure 2.29 Cryptococcus. The capsule stains light blue and the cell wall a reddish color. (Alcian blue–PAS)

pigmented purpuric dermatosis but with more papillary dermal fibrosis and no hemosiderin. In other words, ‘triple P-D resembles double P-D’.

THE DEMONSTRATION OF CRYPTOCOCCI (Fig. 2.29)

- Cryptococci are doubly refractile
- They are mucicarmine positive
- On Alcian blue–PAS, a beautiful contrast is seen between cell wall and capsule
- It does not stain with Congo red.

THE EDGE OF BOWEN’S DISEASE

Pagetoid cells are often present at the edge of Bowen’s disease. They may simulate melanoma or Paget’s disease in small (2 or 3 mm) punch biopsies.

FALSE-NEGATIVE IMMUNOPEROXIDASE

The use of microwaves for fixation may release excess antigens leading to the prozone phenomenon. A false-negative results, although some staining may occur at the periphery of the tumor. The dilution of the antisera used must be changed in these circumstances. Automated staining is another cause.

MISCELLANEOUS HINTS

- Psoriasis is a ‘mitotic disease’. Look for mitoses in basal keratinocytes
- In hypertrophic lichen planus, the lichenoid activity may be confined to the tips of the rete pegs
- Early lichen sclerosis et atrophicus may have lichenoid histological features
- Acantholytic solar keratoses often mimic basal cell carcinoma clinically; they may be resistant to cryotherapy.

The lichenoid reaction pattern ('interface dermatitis')

INTRODUCTION

The lichenoid reaction pattern (lichenoid tissue reaction, interface dermatitis) is characterized histologically by epidermal basal cell damage.¹⁻³ This takes the form of cell death and/or vacuolar change (liquefaction degeneration). The cell death usually involves only scattered cells in the basal layer that become shrunken with eosinophilic cytoplasm. These cells, which have been called Civatte bodies, often contain pyknotic nuclear remnants. Sometimes, fine focusing up and down will reveal smaller cell fragments, often without nuclear remnants, adjacent to the more obvious Civatte bodies.⁴ These smaller fragments have separated from the larger bodies during the process of cell death. Ultrastructural studies have shown that the basal cells in the lichenoid reaction pattern usually die by apoptosis, a comparatively recently described form of cell death, which is quite distinct morphologically from necrosis.^{5,6}

Before discussing the features of apoptosis, mention will be made of the term **'interface dermatitis'**, which is widely used. It has been defined as a dermatosis in which the infiltrate (usually composed mostly of lymphocytes) appears "to obscure the junction when sections are observed at scanning magnification."⁷ The term is not used uniformly or consistently. Some apply it to most dermatoses with the lichenoid tissue reaction. Others use it for the subgroup in which the infiltrate truly obscures the interface (erythema multiforme, fixed drug eruption, paraneoplastic pemphigus, some cases of subacute lupus erythematosus and pityriasis lichenoides). The infiltrate may obscure the interface in lymphomatoid papulosis, but basal cell damage is not invariable. Many apply the term, also, to lichen planus and variants, in which the infiltrate characteristically 'hugs' the basal layer without much extension into the epidermis beyond the basal layer. Crowson *et al.* have expanded the concept of interface dermatitis to include neutrophilic and lymphohistiocytic forms, in addition to the traditional lymphocytic type. They also subdivide the lymphocytic type into a cell-poor type and a cell-rich type.⁸ Erythema multiforme, which they list as a cell-poor variant, is sometimes quite 'cell rich'. The author prefers the traditional term 'lichenoid' for this group of dermatoses because it is applicable more consistently than interface dermatitis and it is less likely to be applied as a 'final sign-out diagnosis', which is often the case with the term interface dermatitis. The term is so entrenched that it is unlikely to disappear from the lexicon of dermatopathology.

In *apoptosis*, single cells become condensed and then fragment into small bodies by an active budding process (Fig. 3.1). In the skin, these condensed apoptotic bodies are known as Civatte bodies (discussed previously). The smaller apoptotic bodies, some of which are beyond the resolution of the light microscope, are usually phagocytosed quickly by adjacent parenchymal cells or by tissue macrophages.⁵ Cell membranes and organelles remain intact for some time in apoptosis, in contradistinction to necrosis where breakdown of these structures is an integral and prominent part of the process. Keratinocytes contain tonofilaments that act as a 'straitjacket' within the cell, and therefore budding and fragmentation are less complete in the skin than they are in other cells in the body undergoing death by apoptosis. This is particularly so if the keratinocyte has accumulated filaments in its cytoplasm, as occurs with its progressive maturation in the epidermis. The term 'dyskeratotic cell' is usually used for these degenerate keratinocytes. The apoptotic bodies that are rich in tonofilaments are usually larger than the others; they tend to 'resist' phagocytosis by parenchymal cells, although some are phagocytosed by macrophages. Others are extruded into the papillary dermis, where they are known as *colloid bodies*. These bodies appear to trap immunoglobulins nonspecifically, particularly the IgM molecule, which is larger than the others. Apoptotic cells can be labeled by the TUNEL (terminal transferase-mediated dUTP nick end labeling) reaction.⁹

Figure 3.1 (A) Apoptosis of a basal keratinocyte in lichen planus. There is surface budding and some redistribution of organelles within the cytoplasm. (Electron micrograph $\times 12,000$) **(B) A tiny budding fragment in which the mitochondria have intact cristae.** ($\times 25,000$)

Some of the diseases included within the lichenoid reaction pattern show necrosis of the epidermis rather than apoptosis; in others, the cells have accumulated so many cytoplasmic filaments prior to death that the actual mechanism – apoptosis or necrosis – cannot be discerned by light or electron microscopy. The term 'filamentous degeneration' has been suggested for these cells;¹⁰ on light microscopy, they are referred to as 'dyskeratotic cells' (discussed previously). Some dermatopathologists use the term 'necrotic keratinocyte' for these cells and also for keratinocytes that are obviously apoptotic. Note that apoptotic keratinocytes have been seen in normal skin, indicating that cell deletion also occurs as a normal physiological phenomenon.¹¹⁻¹³ As

Afford and Randhawa eloquently stated, "Apoptosis is the genetically regulated form of cell death that permits the safe disposal of cells at the point in time when they have fulfilled their intended biological function."¹⁴ It also plays a role in the elimination of the inflammatory infiltrate at the end stages of wound healing.¹⁵

Although it is beyond the scope of this book, readers interested in apoptosis and the intricate mechanisms of its control should read the excellent studies published on this topic.^{16–24} The various 'death receptors', essential effectors of any programmed cell death, were reviewed in 2003.²⁵ An important member of this group is tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), which preferentially induces apoptosis in transformed but not normal cells. It is expressed in normal skin and cutaneous inflammatory diseases.²⁶ Another cell component that plays a role in apoptosis is the mitochondrion. This topic was reviewed in 2006.²⁷

Ackerman has continued to present a minority view that apoptosis is a type of necrosis.²⁸ In reality, each is a distinctive form of cell death.

Vacuolar change (liquefaction degeneration) is often an integral part of the basal damage in the lichenoid reaction. Sometimes it is more prominent than the cell death. It results from intracellular vacuole formation and edema, as well as from separation of the lamina densa from the plasma membrane of the basal cells. Vacuolar change is usually prominent in lupus erythematosus, particularly the acute systemic form, and in dermatomyositis and some drug reactions.

As a consequence of the basal cell damage, there is variable *melanin incontinence* resulting from interference with melanin transfer from melanocytes to keratinocytes, as well as from the death of cells in the basal layer.¹ Melanin incontinence is particularly prominent in some drug-induced and solar-related lichenoid lesions, as well as in patients with marked racial pigmentation.

Another feature of the lichenoid reaction pattern is a variable *inflammatory cell infiltrate*. This varies in composition, density, and distribution according to the disease. An assessment of these characteristics is important in distinguishing the various lichenoid dermatoses. Because apoptosis, unlike necrosis, does not itself evoke an inflammatory response, it can be surmised that the infiltrate in those diseases with prominent apoptosis is of pathogenetic significance and not a secondary event.⁵ Furthermore, apoptosis is the usual method of cell death resulting from cell-mediated mechanisms, whereas necrosis and possibly vacuolar change result from humoral factors, including the deposition of immune complexes.

One study has given some insight into the possible mechanisms involved in the variability of expression of the lichenoid tissue reaction in several of the diseases within this group. The study examined the patterns of expression of the intercellular adhesion molecule-1 (ICAM-1).²⁹ Keratinocytes in normal epidermis have a low constitutive expression of ICAM-1, rendering the normal epidermis resistant to interaction with leukocytes. Therefore, induction of ICAM-1 expression may be an important factor in the induction of leukocyte-dependent damage to keratinocytes.²⁹ In lichen planus, ICAM-1 expression is limited to basal keratinocytes, whereas in subacute cutaneous lupus erythematosus there is diffuse epidermal ICAM-1 expression, sometimes with basal accentuation. This pattern is induced by ultraviolet radiation and possibly mediated by tumor necrosis factor- α (TNF- α). In erythema multiforme, there is strong basal expression of ICAM-1, with cell surface accentuation and similar pockets of suprabasal expression, probably induced by herpes simplex virus infection.²⁹

Other molecules appear to play important roles in lichenoid dermatitis. IKKB, a subunit of the I κ B kinase complex, is required for activation of NF- κ B, a protein that controls DNA transcription. In an animal model, overexpression of IKK β results in chronic inflammation with macrophages and CD45⁺ cells, interface dermatitis, and increased production of inflammatory cytokines by keratinocytes. This process apparently occurs independently of T and B lymphocytes.³⁰ The type 1 interferon (IFN) system plays an important role in the interface

dermatitis associated with autoimmune diseases, mediating a cytotoxic attack on basal keratinocytes. Evidence for this is the finding of IFN-inducible chemokine CXCL10 expression in the same location where CXCR3⁺ cytotoxic lymphocytes invade the epidermal basilar layer.³¹ Using a model of reconstructed human epidermis, Farley *et al.* explored the important roles of the Fas ligand (the expression of which by donor T cells may be essential for cutaneous acute graft-versus-host reaction) and IFN- γ . These investigators found that cytooid body formation and epidermal expression of ICAM-1 could be attributed to IFN- γ , whereas hypergranulosis was triggered by the Fas ligand, and vacuolar degeneration of the basilar layer appeared to be triggered by both the Fas ligand and IFN- γ .³²

In summary, the lichenoid reaction pattern includes a heterogeneous group of diseases that have in common basal cell damage.³³ The histogenesis is also diverse and includes cell-mediated and humoral immune reactions and possibly ischemia in one condition. A discussion of the mechanisms involved in producing apoptosis is included in several of the diseases that follow. Scattered apoptotic keratinocytes can also be seen in the sunburn reaction in response to ultraviolet radiation;^{34,35} these cells are known as 'sunburn cells'.³⁶ A specific histological diagnosis can usually be made by attention to such factors as:

- the nature and extent of the basal damage;
- the nature, composition, and distribution of the inflammatory reaction;
- the amount of melanin incontinence that results from the basal damage;
- the coexistence of another tissue reaction;³⁷ and;
- other individual characteristics.²

These points are considered further in [Tables 3.1–3.3](#).

A discussion of the various lichenoid (interface) dermatoses follows. The conditions listed as 'other lichenoid (interface) diseases' are discussed only briefly because they are considered in detail in other chapters.

LICHENOID (INTERFACE) DERMATOSES

LICHEN PLANUS

Lichen planus, a relatively common eruption of unknown etiology, displays violaceous, flat-topped papules, which are usually pruritic.^{38,39} A network of fine white lines (Wickham's striae) may be seen on the surface of the papules. There is a predilection for the flexor surface of the wrists, the trunk, the thighs, and the genitalia. Palmoplantar lichen planus appears to be more common than once thought.^{40,41} It is one of the most disabling, painful, and therapy-resistant variants of lichen planus.⁴² Oral lesions are common; rarely, the esophagus is also involved.^{43,44} Lesions localized to the lip,⁴⁵ vulva,^{46,47} and an eyelid⁴⁸ have been reported. Lichen planus localized to a radiation field may represent an isomorphic response.^{49,50} It has also developed in a healed herpes zoster scar.⁵¹ Nail changes occur^{52–55} and, as with oral lesions, these may be the only manifestations of the disease.^{56,57} Clinical variants include atrophic, annular, hypertrophic, linear, zosteriform,^{58–60} erosive, oral, actinic, follicular, erythematous, and bullous forms. They are discussed further later. An eruptive variant also occurs.⁶¹ Spontaneous resolution of lichen planus is usual within 12 months, although postinflammatory pigmentation may persist for some time afterwards.⁶²

Familial cases are uncommon, and rarely these are associated with HLA-D7.^{63–66} An association with HLA-DR1 has been found in non-familial cases.⁶⁷ There is an increased frequency of HLA-DR6 in Italian patients with hepatitis C virus-associated oral lichen planus.⁶⁸ Lichen planus is rare in children,^{69–76} but some large series have been

Table 3.1 Key histopathological features of various lichenoid diseases	
Disease	Histopathological features
Lichen planus	Prominent Civatte bodies, band-like inflammatory infiltrate, wedge-shaped hypergranulosis. Hypertrophic form has changes limited to the tips of the acanthotic downgrowths and often superadded lichen simplex chronicus. The infiltrate extends around hair follicles in lichen planopilaris. Pigment incontinence is conspicuous in erythema dyschroicum perstans.
Lichen nitidus	Focal (papular) lichenoid lesions; some giant cells; dermal infiltrate often ‘clasped’ by acanthotic downgrowths.
Lichen striatus	Clinically linear; irregular and discontinuous lichenoid reaction; infiltrate sometimes around follicles and sweat glands.
Lichen planus-like keratosis	Solitary; prominent Civatte body formation; solar lentigo often at margins.
Lichenoid drug eruptions	Focal parakeratosis; eosinophils, plasma cells and melanin incontinence may be features. Deep extension of the infiltrate occurs in photolichenoid lesions.
Fixed drug eruptions	Interface-obscuring infiltrate, often extends deeper than erythema multiforme; cell death often above basal layer; neutrophils often present.
Erythema multiforme	Interface-obscuring infiltrate; sometimes subepidermal vesiculation and variable epidermal cell death.
Graft-versus-host disease	Basal vacuolation; scattered apoptotic keratinocytes, sometimes with attached lymphocytes (‘satellite cell necrosis’); variable lymphocytic infiltrate.
Lupus erythematosus	Mixed vacuolar change and Civatte bodies. SLE has prominent vacuolar change and minimal cell death. Discoid lupus away from the face has more cell death and superficial and deep infiltrate; mucin; follicular plugging; basement membrane thickening. Some cases resemble erythema multiforme with cell death at all layers.
Dermatomyositis	May resemble acute lupus with vacuolar change, epidermal atrophy, some dermal mucin; infiltrate usually superficial and often sparse.
Poikilodermas	Vacuolar change; telangiectasia; pigment incontinence; late dermal sclerosis.
Pityriasis lichenoides	Acute form combines lymphocytic vasculitis with epidermal cell death; interface-obscuring infiltrate; focal hemorrhage; focal parakeratosis.
Paraneoplastic pemphigus	Erythema multiforme-like changes with suprabasal acantholysis and clefting; subepidermal clefting sometimes present.

published.^{77–79} Lichen planus has been reported in association with immunodeficiency states,⁸⁰ internal malignancy,^{81,82} including thymoma,⁸³ Still’s disease,⁸⁴ primary biliary cirrhosis,^{85,86} hypothyroidism,⁸⁷ peptic ulcer (but not *Helicobacter pylori* infection),⁸⁸ chronic hepatitis C infection,^{89–99} hepatitis B vaccination,^{100–109} influenza vaccination,¹¹⁰ herpesvirus type 7 (HHV-7) replication,¹¹¹ simultaneous measles–mumps–rubella and diphtheria–tetanus–pertussis–polio vaccinations,¹¹² stress,¹¹³ vitiligo,¹¹⁴ pemphigus,¹¹⁵ porphyria cutanea tarda,¹¹⁶ radiotherapy,¹¹⁷ ulcerative colitis,¹¹⁸ chronic giardiasis,¹¹⁹ a Becker’s nevus,¹²⁰ and lichen sclerosus et atrophicus with coexisting morphea.¹²¹ Despite the association between lichen planus and hepatitis C (HCV) infection, its incidence in patients with lichen planus in some areas of the world is not increased compared with that of a control group.^{122,123} Lichen planus patients have a significantly higher risk than controls of being

Table 3.2 Diagnoses associated with various pathological changes in the lichenoid reaction pattern	
Pathological change	Possible diagnoses
Vacuolar change	Lupus erythematosus, dermatomyositis, drugs and poikiloderma
Interface-obscuring infiltrate	Erythema multiforme, fixed drug eruption, pityriasis lichenoides (acute), paraneoplastic pemphigus, lupus erythematosus (some)
Purpura	Lichenoid purpura
Cornoid lamella	Porokeratosis
Deep dermal infiltrate	Lupus erythematosus, syphilis, drugs, photolichenoid eruption
‘Satellite cell necrosis’	Graft-versus-host disease, eruption of lymphocyte recovery, erythema multiforme, paraneoplastic pemphigus, regressing plane warts, drug reactions
High apoptosis	Phototoxic reactions, adult-onset Still’s disease, acrokeratosis paraneoplastica
Prominent pigment incontinence	Poikiloderma, drugs, ‘racial pigmentation’ and an associated lichenoid reaction, erythema dyschroicum perstans and related entities
Eccrine duct involvement	Erythema multiforme (drug induced), lichen striatus, keratosis lichenoides chronica, periflexural exanthem of childhood

Table 3.3 Diseases with the lichenoid and one or more coexisting tissue reaction patterns	
Additional pattern	Possible diagnoses
Spongiotic	Drug reactions (see spongiotic drug reactions), lichenoid contact dermatitis, lichen striatus, late-stage pityriasis rosea, superantigen ‘id’ reactions
Granulomatous	Lichen nitidus, lichen striatus (rare), lichenoid sarcoidosis, hepatobiliary disease, endocrinopathies, infective reactions including secondary syphilis, herpes zoster infection, HIV infection, tinea capitis, <i>Mycobacterium marinum</i> , and <i>M. haemophilum</i> ; drug reactions (often in setting of Crohn’s disease or rheumatoid arthritis – atenolol, allopurinol, captopril, cimetidine, enalapril, hydroxychloroquine, simvastatin, sulfa drugs, tetracycline, diclofenac, erythropoietin)
Vasculitic	Pityriasis lichenoides, perniosis (some cases), pigmented purpuric dermatosis (lichenoid variant), persistent viral reactions, including herpes simplex
Vasculitic/spongiotic	Gianotti–Crosti syndrome, some other viral/putative viral diseases, rare drug reactions

HCV seropositive, and there is a similar odds ratio of having lichen planus among HCV patients; this appears to only partly depend on geographic effect.¹²⁴ A large European study showed that lichen planus is associated with HCV but not with HBV.¹²⁵ On the other hand, although HCV and oral lichen planus are significantly associated in a number of studies, most patients with oral lichen planus are not affected by HCV.¹²⁶ The exacerbation or appearance of lichen planus during the treatment of HCV infection and other diseases with IFN- α has been reported.¹²⁷ Furthermore, effective therapy for the HCV does not clear the lichen planus.¹²⁸ Reports linking lichen planus to infection with human papillomavirus may be a false-positive result.^{129,130}

Squamous cell carcinoma is a rare complication of the oral and vulval cases of lichen planus and of the hypertrophic and ulcerative variants (see later).^{131–135} One study found no significant transformation risk of cutaneous lichen planus to squamous cell carcinoma, although there is a significant risk of malignant transformation in mucosal lichen planus.¹³⁶ A contact allergy to metals, flavorings, and plastics may be important in the etiology of oral lichen planus.¹³⁷ The role of mercury in dental amalgams is discussed further later.

Cell-mediated immune reactions appear to be important in the pathogenesis of lichen planus.¹³⁸ It has been suggested that these reactions are precipitated by an alteration in the antigenicity of epidermal keratinocytes, possibly caused by a virus or a drug or by an allogeneic cell.¹³⁹ Keratinocytes in lichen planus express HLA-DR on their surface, and this may be one of the antigens that has an inductive or perpetuating role in the process.^{140–142} Keratinocytes also express fetal cytokeratins (CK13 and CK8/18), but whether they are responsible for triggering the T-cell response is speculative.¹⁴³ The cellular response initially consists of CD4⁺ lymphocytes;¹⁴⁴ they are also increased in the peripheral blood.¹⁴⁵ In recent years, attention has focused on the role of cytotoxic CD8⁺ lymphocytes in a number of cell-mediated immune reactions in the skin. They appear to play a significant role as the effector cell, whereas the CD4⁺ lymphocyte, usually present in greater numbers,¹⁴⁶ plays its traditional 'helper' role. In lichen planus, CD8⁺ cells appear to recognize an antigen associated with MHC class I on lesional keratinocytes, resulting in their death by apoptosis.¹⁴⁷ *Bcl-2*, a proto-oncogene that protects cells from apoptosis, is increased in lichen planus.¹⁴⁸ It may allow some cells to escape apoptosis, prolonging the inflammatory process.¹⁴⁸ The recruitment of lymphocytes to the interface region may be the result of the chemokine MIG (monokine induced by IFN- γ).¹⁴⁹ Lymphokines produced by these T lymphocytes – including IFN- γ , interleukins (IL)-1 β , -4 and -6, perforin,¹⁵⁰ granzyme B,¹⁵¹ granulysin,¹⁵² T-cell-restricted intracellular antigen (Tia-1), and tumor necrosis factor – may have an effector role in producing the apoptosis of keratinocytes.^{153,154} The other pathway involves the binding of Fas ligand to Fas, which triggers a caspase cascade.^{155,156} In both oral and cutaneous lichen planus, CD8⁺ cells predominate in the epithelial and subepithelial compartments, with CD4⁺ cells playing a helper role by secretion of Th1 cytokines. Activated CD8⁺ cells promote basilar keratinocyte apoptosis through either granzyme B or Fas/Fas ligand pathways.¹⁵⁷ As one possible explanation of how this mechanism might work in lichen planus, elevated osteopontin levels may upregulate CD44, with resultant T-cell resistance to apoptosis and accumulation of activated T cells in lichen planus lesions.¹⁵⁸ Gene expression profiling in lichen planus has found that type I IFN inducible genes are significantly expressed.¹⁵⁹ Plasmacytoid dendritic cells appear to be a major source of these type I IFNs in lichen planus. They play a major role in cytotoxic skin inflammation by increasing the expression of IPIIO/CXCR3 and recruiting effector cells via CXCR3.¹⁶⁰ The CXCR3 ligand, CXCL9, is the most significant marker for lichen planus.¹⁵⁹ A unique subclass of cytotoxic T lymphocyte ($\gamma\delta$) is also found in established lesions.¹⁶¹ Langerhans cells are increased, and it has been suggested that these cells initially process the foreign antigen.¹⁴¹ Factor XIIIa-positive cells and macrophages expressing lysozyme are found in the dermis.¹⁴⁴

There is evidence that expression of the microRNAs, miRNA-146a and miRNA-155, is increased in lesions of oral lichen planus. MicroRNAs are known to participate in immune response regulation.¹⁶²

Increased oxidative stress, increased lipid peroxidation, and an imbalance in the antioxidant defense system are present, but their exact role in the pathogenesis of lichen planus is unknown.¹⁶³

Matrix metalloproteinases may play a concurrent role by destroying the basement membrane.¹⁶⁴ Evidence from an animal model suggests that keratinocytes require cell survival signals, derived from the basement membrane, to prevent the onset of apoptosis.¹⁶⁵ In oral lichen

planus, MMP-1 and MMP-3 may be principally associated with erosion development.¹⁶⁶ Altered levels of heat shock proteins are found in the epidermis in lichen planus.¹⁶⁷

Most studies have found no autoantibodies and no alteration in serum immunoglobulins in lichen planus.¹⁶⁸ However, a lichen planus-specific antigen has been detected in the epidermis, and a circulating antibody to it has been found in the serum of individuals with lichen planus.^{169,170} Its pathogenetic significance remains uncertain. Antibodies to desmoplakins I and II have been found in oral and genital lesions, possibly representing epitope spreading.¹⁷¹

Replacement of the damaged basal cells is achieved by an increase in actively dividing keratinocytes in both the epidermis and the skin appendages. This is reflected in the pattern of keratin expression, which resembles that seen in wound healing; cytokeratin 17 (CK17) is found in suprabasal keratinocytes.¹⁷²

Treatment of lichen planus

Potent topical corticosteroids remain the treatment of choice for lichen planus in patients with classic and localized disease. For widespread disease and mucosal lesions, a short course of systemic corticosteroids may provide some relief.¹⁷³ Cyclosporine (ciclosporin), hydroxychloroquine, retinoids, dapsone, mycophenolate mofetil,¹⁷⁴ sulfasalazine,¹⁷⁵ alefacept,¹⁷⁶ and efalizumab¹⁷⁷ have all been used at various times. Mycophenolate mofetil has been shown to be effective in severe ulcerative lichen planus.¹⁷⁸ Erosive oral disease has been treated with tacrolimus mouthwash,¹⁷⁹ whereas erosive flexural lichen planus has responded to thalidomide and 0.1% tacrolimus ointment.¹⁸⁰ Palmoplantar disease may be resistant to treatment and require cyclosporine.⁴¹

Histopathology¹⁸¹

The basal cell damage in lichen planus takes the form of multiple, scattered Civatte bodies (Fig. 3.2). Eosinophilic colloid bodies, which are PAS positive and diastase resistant, are found in the papillary dermis (Fig. 3.3). They measure approximately 20 μ m in diameter. The basal damage is associated with a band-like infiltrate of lymphocytes and some macrophages that press against the undersurface of the epidermis (Fig. 3.4). Occasional lymphocytes extend into the basal layer, where they may be found in close contact with basal cells and sometimes with Civatte bodies. The infiltrate tends to obscure the interface but does not extend into the mid-epidermis. Karyorrhexis is sometimes seen in the dermal infiltrate.¹⁸² Rarely, plasma cells can be found in cutaneous lesions,^{183–186} but most often they are not identified – a feature that can be useful in differential diagnosis. In exceptional cases, they can be numerous.^{184–186} In some instances, plasma cells may be found because cutaneous lesions have arisen in anatomic sites where these cells tend to be prevalent, such as the face, posterior neck, intertriginous sites, and pretibial areas. Although they are usually present in lesions adjacent to or on mucous membranes, plasma cells are sometimes surprisingly sparse even in these locations. There is variable melanin incontinence, but this is most conspicuous in lesions of long duration and in dark-skinned people.

Other characteristic epidermal changes include hyperkeratosis, wedge-shaped areas of hypergranulosis related to the acrosyringia and acrotrichia, and variable acanthosis. At times, the rete ridges become pointed, imparting a 'sawtooth' appearance to the lower epidermis. There is sometimes mild hypereosinophilia of keratinocytes in the malpighian layer. Small clefts (Caspary-Joseph spaces)¹⁸⁷ may form at the dermoepidermal junction secondary to the basal damage. The eccrine duct adjacent to the acrosyringium is sometimes involved.^{188,189} A variant in which the lichenoid changes were localized entirely to the acrosyringium has been reported.¹⁹⁰ Transepidermal elimination with perforation is another rare finding.¹⁹¹ The formation of milia may be a late complication.¹⁹²

Figure 3.2 Lichen planus. Two apoptotic keratinocytes (Civatte bodies) are present in the basal layer of the epidermis. An infiltrate of lymphocytes touches the undersurface of the epidermis. (H&E)

Figure 3.3 Lichen planus. There are numerous colloid bodies in the papillary dermis. (H&E)

Figure 3.4 Lichen planus. A band-like infiltrate of lymphocytes fills the papillary dermis and touches the undersurface of the epidermis. (H&E)

Figure 3.5 Lichen planus. A band of fibrin involves the basement membrane zone and extends into the papillary dermis. (Direct immunofluorescence)

Ragaz and Ackerman studied the evolution of lesions in lichen planus.¹⁸¹ They found an increased number of Langerhans cells in the epidermis in the very earliest lesions, before there was any significant infiltrate of inflammatory cells in the dermis. In resolving lesions, the infiltrate is less dense, and there may be minimal extension of the inflammatory infiltrate into the reticular dermis.

As previously mentioned, some diseases exhibiting the lichenoid tissue reaction may also show features of another tissue reaction pattern as a major or minor feature. These conditions are listed in [Table 3.3](#).

Direct immunofluorescence of involved skin shows colloid bodies in the papillary dermis, staining for complement and immunoglobulins, particularly IgM. An irregular band of fibrin is present along the basal layer in most cases. Often there is irregular extension of the fibrin into the underlying papillary dermis ([Fig. 3.5](#)). One study found colloid bodies in 60% of cases of lichen planus, whereas fibrin was present in all cases.¹⁹³ Immunofluorescent analysis of the basement membrane zone, using a range of antibodies, suggests that disruption occurs in the lamina lucida region.¹⁹⁴ Other studies have shown a disturbance in the epithelial anchoring system.¹⁹⁵

Electron microscopy

Ultrastructural studies have confirmed that lymphocytes attach to basal keratinocytes, resulting in their death by apoptosis.^{4,5,196} Many cell fragments, beyond the limit of resolution of the light microscope, are formed during the budding of the dying cells. The cell fragments are phagocytosed by adjacent keratinocytes and macrophages.¹⁹⁷ The large tonofilament-rich bodies that result from redistribution of tonofilaments during cell fragmentation appear to resist phagocytosis and are extruded into the upper dermis, where they are recognized on light microscopy as colloid bodies.¹⁹⁸ Various studies have confirmed the epidermal origin of these colloid bodies.^{199,200} There is a suggestion from some experimental work that sublethal injury to keratinocytes may lead to the accumulation of tonofilaments in their cytoplasm. Some apoptotic bodies contain more filaments than would be accounted for by a simple redistribution of the usual tonofilament content of the cell.

Differential diagnosis

The most important distinction is between lichen planus and *lupus erythematosus*. This can be a particular problem with scalp lesions, where the infiltrates of lichen planopilaris can closely resemble the follicular involvement of lupus erythematosus (see later), or with lupus lesions that display dense superficial dermal infiltrates. Atrophic lichen planus can bear a resemblance to poikilodermatous lesions of lupus erythematosus, whereas hypertrophic lesions of discoid lupus erythematosus can resemble their hypertrophic lichen planus counterpart. In contrast to lichen planus, lupus erythematosus most often shows epidermal atrophy, persistent vacuolar change of the basilar layer rather than basal keratinocyte loss (with flattening or 'sawtooth' of the epidermal base), basement membrane zone thickening (especially in lesions of at least 6 months' duration), a deep as well as superficial dermal infiltrate that involves vessels and sweat glands as well as follicles, and often interstitial dermal mucin deposition. In addition, a degree of panniculitis is seen in a significant number of lupus cases, consisting of mild patchy lymphocytic infiltrates, mucin deposition, or lipoatrophy; those changes are not seen in lichen planus. The most common problems in differential diagnosis arise with *lichenoid keratoses* and *lichenoid drug eruptions*. These entities are further discussed later. Most of the other lichenoid dermatoses lack the full constellation of findings of lichen planus. *Lichenoid actinic keratosis*, or *actinic cheilitis*, shows basilar keratinocyte atypia that is disproportionate to that expected as a response to inflammation alone, and often the atypical changes extend laterally beyond the zone of most intense dermal inflammation. Fully developed *lichen sclerosus* is quite distinctive, but early disease may show a band-like superficial infiltrate partly obscuring the dermal–epidermal interface; together with vacuolar alteration of the basilar layer, this can produce an image somewhat reminiscent of lichen planus. However, the loss of basilar keratinocytes with sawtooth or flattening of the epidermal base is often not a feature in lichen sclerosus, and dermal edema or early homogenization of papillary collagen may be evident even in early stages of the disease. *Poikilodermatous mycosis fungoides* with a heavy, band-like infiltrate could be confused with the atrophic variety of lichen planus, but atypical lymphocytes, 'lining up' of singly dispersed lymphocytes along the basilar layer, and wiry papillary dermal collagen may be identified – findings not expected in lichen planus. In *erythema multiforme* and *fixed drug eruption*, dense, band-like infiltrates obscuring the dermal–epidermal interface would be unusual. The rapid onset of these conditions usually means that the epidermis is of approximately normal thickness, and an ordinary-appearing, basket-woven stratum corneum is often preserved. Furthermore, apoptotic keratinocytes in lichen planus are usually observed at the basilar layer or within the papillary dermis, where they are often arranged in clusters; in erythema multiforme and fixed drug eruption, apoptotic keratinocytes are usually found widely scattered throughout all levels of the epidermis. Keratosis lichenoides

chronica and lichen striatus often show dermal infiltrates in patchy distribution, with involvement of the mid to deep dermis and sometimes perieccrine lymphocytic infiltration.

Direct immunofluorescence can sometimes be helpful in differential diagnosis. The combination of junctional apoptotic bodies staining for IgM and a fibrin band along the dermal–epidermal junction is characteristic of lichen planus. Although it can be mimicked by other lichenoid dermatoses, these features differ from lupus erythematosus, which when positive shows particulate, thick linear, or occasionally linear deposition of immunoglobulin, C3 complement, or fibrin along the dermal–epidermal junction. Occasionally, an antinuclear antibody can be observed in the highlighting of keratinocyte nuclei with antibodies to IgG. Therefore, this procedure can be helpful in cases of lichen planus–lupus erythematosus overlap. Immunofluorescent study can also be useful when evaluating mucous membrane biopsies, where the differential diagnosis includes both lichen planus and cicatricial pemphigoid (one example is the condition known as desquamative gingivitis, which can be a manifestation of either disease). In contrast to lichen planus, cicatricial pemphigoid would show linear deposition of immunoglobulin and/or C3 complement along the epithelial–stromal interface.

LICHEN PLANUS VARIANTS

A number of clinical variants of lichen planus occur. In some, typical lesions of lichen planus are also present. These variants are discussed in further detail here.

Atrophic lichen planus

Atrophic lesions may resemble porokeratosis clinically. Typical papules of lichen planus are usually present at the margins. A rare form of atrophic lichen planus is composed of annular lesions.^{201–205} It is composed of violaceous plaques of annular morphology with central atrophy.²⁰⁶ Hypertrophic lichen planus has been reported at the edge of a plaque of annular atrophic lichen planus.²⁰⁷ Experimentally, there is an impaired capacity of the atrophic epithelium to maintain a regenerative steady state.

Histopathology

The epidermis is thin and there is loss of the normal rete ridge pattern. The infiltrate is usually less dense than in typical lichen planus. It may be lost in the center of the lesions.

Hypertrophic lichen planus

Hypertrophic lesions are usually confined to the shins, although sometimes they are more generalized.²⁰⁸ They appear as single or multiple pruritic plaques, which may have a verrucous appearance;²⁰⁹ they usually persist for many years. A case from the vulvar region resembled condylomata acuminata.²¹⁰ Rarely, squamous cell carcinoma develops in lesions of long standing.^{211–214} Cutaneous horns, keratoacanthoma, and verrucous carcinoma may also develop in hypertrophic lichen planus.^{215–217}

Hypertrophic lichen planus has been reported in several patients infected with the human immunodeficiency virus.²¹⁸ It also occurs in patients with HCV infection.²¹⁹ It may occur in children.²²⁰

Histopathology

The epidermis shows prominent hyperplasia and overlying orthokeratosis (Fig. 3.6). At the margins there is usually psoriasiform hyperplasia representing concomitant changes of lichen simplex chronicus secondary to the rubbing and scratching. If the epidermal hyperplasia is severe, it may mimic a squamous cell carcinoma on a shave biopsy.²²¹

Figure 3.6 Hypertrophic lichen planus. The epidermis shows irregular hyperplasia. The dermal infiltrate is concentrated near the tips of the rete ridges. (H&E)

Vertically oriented collagen ('vertical-streaked collagen') is present in the papillary dermis in association with the changes of lichen simplex chronicus.

Differential diagnosis

A common problem is the distinction between hypertrophic lichen planus and keratoacanthoma or well-differentiated squamous cell carcinoma. A history of occurrence over the pretibial areas and of more typical lesions of lichen planus elsewhere would of course be helpful. Microscopically, the lack of significant cytologic atypia in the face of a lichenoid host tissue reaction is a clue to the diagnosis of hypertrophic lichen planus. When compared to hypertrophic lichen planus, keratoacanthoma has a comparable proliferative index, but it shows increased expression of p53 and, as a significant difference from hypertrophic lichen planus, perforating elastic fibers, which can be demonstrated with the Verhoeff-van Gieson stain.²²²

The basal cell damage is usually confined to the tips of the rete ridges and may be missed on casual observation (Fig. 3.7). The infiltrate is not as dense or as band-like as in the usual lesions of lichen planus. A few eosinophils and plasma cells may be seen in some cases in which the ingestion of β -blockers can sometimes be incriminated.

Xanthoma cells have been found in the dermis, localized to a plaque of hypertrophic lichen planus, in a patient with secondary hyperlipidemia.²²³ This is an example of dystrophic xanthomatization.

Annular lichen planus

Annular lichen planus is one of the rarer clinical forms of lichen planus. In a series of 20 patients, published some years ago, 18 were men and 2 women. Sites of involvement included the axilla, penis, extremities, and groin.²²⁴ Eighteen of the patients had purely annular lesions, whereas 2 of the patients had a few purple polygonal papules as well. The majority of lesions showed central clearing with a purple to white annular edge. Lesions varied from 0.5 to 2.5 cm in diameter. (Atrophic annular lesions were discussed with atrophic lichen planus (see p. 43)). The majority of patients were asymptomatic. Oral and genital lesions have been reported in annular lichen planus.²²⁵⁻²²⁸ The cases reported as **annular lichenoid dermatitis of youth** appear to be a distinct entity, but further reports will be necessary to clarify its exact position in the spectrum of lichen planus.²²⁹ The lesions are persistent erythematous macules and annular patches mostly localized on the groin and flanks.

Figure 3.7 Hypertrophic lichen planus. There are a number of Civatte bodies near the tips of the rete ridges. (H&E)

In all cases, the clinical picture has been suggestive of morphea, mycosis fungoides, or annular erythema, but these conditions could be excluded on the basis of the distinctive superficial lichenoid reaction with massive necrosis/apoptosis of the keratinocytes at the tips of the rete ridges.²²⁹ Patch testing has given negative results.²³⁰

Linear lichen planus

Linear lichen planus is a rare variant that must be distinguished from linear nevi and other dermatoses with linear variants.^{231,232} It occurs in less than 0.5% of patients with lichen planus.²³³ Linear lichen planus usually involves the limbs. It may follow the lines of Blaschko.^{234,235} It has been reported in association with hepatitis C infection,²³³ HIV infection,²³⁶ and metastatic carcinoma.²³⁷ There have been several cases described as lichen planus pigmentosus in a linear distribution.^{238,239} There is also a zosteriform variant of lichen planus, in which lesions form along dermatomes or in a zonal distribution. In one report, varicella-zoster viral antigens were detected in eccrine epithelium of zosteriform lesions.²⁴⁰ Sometimes, linear lesions are associated with disseminated nonsegmental papules of ordinary lichen planus. The linear lesions are usually more pronounced in these combined cases.²⁴¹

Ulcerative (erosive) lichen planus

Ulcerative lichen planus (erosive lichen planus) is characterized by ulcerated and bullous lesions on the feet.^{242,243} Mucosal lesions, alopecia, and more typical lesions of lichen planus are sometimes present. Squamous cell carcinoma may develop in lesions of long standing. Variants of ulcerative lichen planus involving the perineal region,²⁴⁴ penis,²⁴⁵ the mouth,²⁴⁶ or the vulva, vagina, and mouth – the vulvovaginal-gingival syndrome^{46,247-250} – have been reported. A patient with erosive lesions of the flexures has been reported.²⁵¹

Castleman's tumor (giant or angiofollicular lymph node hyperplasia) and malignant lymphoma are rare associations of erosive lichen planus.^{252,253} long-term therapy with hydroxyurea and infection with hepatitis C are others.^{254,255} Screening for hepatitis C and B has not been considered necessary for vulval lichen planus in some countries.²⁵⁶

Antibodies directed against a nuclear antigen of epithelial cells have been reported in patients with erosive lichen planus of the oral mucosa.²⁵⁷ Weak circulating basement membrane zone antibodies are also present.²⁵⁸

High-potency topical corticosteroids have been used to treat erosive lichen planus. Relief of symptoms was obtained in 71% of cases of vulvar disease in one series.²⁵⁹ A good response to topical tacrolimus, particularly in vulvar disease, has been achieved in recent years.^{260–263} A randomized, double-blind control trial of topical thalidomide showed efficacy in erosive oral lichen planus.²⁶⁴ Azathioprine, retinoids, dapsone, methotrexate, and hydroxychloroquine have also been used, but there have been no controlled trials of these various treatments.^{256,265} Photodynamic therapy can also be used.

Penile erosive lichen planus responded to circumcision in one case.²⁶⁶

Histopathology

There is epidermal ulceration with more typical changes of lichen planus at the margins of the ulcer. Plasma cells are invariably present in cases involving mucosal surfaces. Lymphocytes are the predominant cell type in reticular and erosive forms of oral lichen planus and are more frequent in the latter; in addition, apoptosis is comparatively diminished among inflammatory cells in the erosive cases.²⁶⁷ Eosinophils were prominent in the oral lesions of a case associated with methyl dopa therapy. In erosive lichen planus of the vulva, there is widespread disruption in several basement membrane zone components, including hemidesmosomes and anchoring fibrils.²⁶⁸

Oral lichen planus

Oral lichen planus has a prevalence of approximately 0.5–2%. It is a disease of middle-aged and older persons, with a female predominance.²⁶⁹ The disease may persist for many years despite treatment. Spontaneous remission is rare.²⁷⁰

There is a low prevalence of oral lichen planus among HCV-infected patients;^{271–273} the keratotic form of oral lichen planus is more prevalent in this disease.²¹⁹

There has been a resurgence of interest in the role of an allergy to mercury in dental amalgams in the pathogenesis of oral lichen planus. Dental plaque and calculus, which have also been shown to contain mercury, are also associated with the disease.²⁷⁴ It appears that in cases unassociated with cutaneous lichen planus, oral lichen planus may often be cleared by the partial or complete removal of amalgam fillings, if there is a positive patch test reaction to mercury compounds.^{269,275} Because mercury-associated disease does not have all the clinical and/or histological features of oral lichen planus, the term 'oral lichenoid lesion' is sometimes used for these cases.²⁷³ In one case, lichen planus developed in a herpes zoster scar on the face following an amalgam (mercury) filling.²⁷⁶ Oral squamous cell carcinoma is a rare complication of oral lichen planus.²⁷⁰ It appears that desmocollin-1 expression in oral atrophic lichen planus is a powerful predictor of the development of dysplasia, whereas desmocollin-1 and E-cadherin expression are predictors of the development of cancer.²⁷⁷

Histopathology

Oral lichen planus mimics to varying degrees the changes seen in cutaneous disease. The infiltrate is usually quite heavy, and it may contain plasma cells, particularly in erosive forms when neutrophils may also be present. Both cells are also found in amalgam-associated disease. Apoptotic keratinocytes tend to occur at a slightly higher level in the mucosa than they do in the cutaneous form, possibly a reflection of amalgam-related cases. Features said to be more likely in amalgam-associated disease are deep extension of the infiltrate, perivascular extension of the infiltrate, and the presence of plasma cells and neutrophils in the connective tissue.²⁷⁸

Erythema dyschromicum perstans

Erythema dyschromicum perstans (ashy dermatosis, lichen planus pigmentosus)²⁷⁹ is a slowly progressive, asymptomatic, ash-colored or

brown macular hyperpigmentation^{280–282} that has been reported from most areas of the world; it is most prevalent in Latin America.²⁸³ Lesions are often quite widespread, although there is a predilection for the trunk and upper limbs. Unilateral²⁸⁴ and linear lesions²⁸⁵ have been described. Periorbital hyperpigmentation is a rare presentation of this disease.²⁸⁶ Activity of the disease may cease after several years. Resolution is more likely in children than in adults.^{287,288} It has been proposed that 'erythema dyschromicum perstans' should be used when lesions have, or have previously had, an erythematous border, whereas 'ashy dermatosis' should be used for other cases without this feature.²⁸⁹ Most clinicians regard the terms as synonymous.

Erythema dyschromicum perstans has been regarded as a macular variant of lichen planus²⁹⁰ on the basis of the simultaneous occurrence of both conditions in several patients^{282,291,292} and similar immunopathological findings.^{293,294} Both paraphenylenediamine and aminopenicillins have been incriminated in its etiology,^{287,290} although this has not been confirmed. This condition has also been reported in patients with HIV infection²⁹⁵ and those with HCV infection.²⁹⁶ There appears to be a genetic susceptibility to the disease. In one Mexican study, there was a significant increase in HLA-DR4, particularly the *0407 subtype, in patients with the disease.²⁸³

Lichen planus pigmentosus, originally reported from India, is thought by some to be the same condition,^{281,290} although this has been disputed.^{289,297–299} As noted previously, a linear variant has been reported.³⁰⁰ In a study of 124 patients from India with lichen planus pigmentosus, the face and neck were the most common sites affected, with pigmentation varying from slate gray to brownish black.³⁰¹ Lichen planus was also present in 19 patients.³⁰¹ The term 'lichen planus pigmentosus inversus' has been used for cases with predominant localization of the disease in intertriginous areas.^{302–304} Lichen planus pigmentosus has been reported in association with a head and neck cancer and with concurrent acrokeratosis paraneoplastica (see p. 590). Both conditions cleared after treatment of the cancer.³⁰⁵

Various therapies have been tried for erythema dyschromicum perstans, but with little benefit. They include sun protection, chemical peels, corticosteroids, and chloroquine.³⁰⁶ Some patients have responded to dapsone³⁰⁶ and to clofazimine.³⁰⁷

Histopathology²⁸⁰

In the active phase, there is a lichenoid tissue reaction with basal vacuolar change and occasional Civatte bodies (Fig. 3.8). The infiltrate is usually quite mild in comparison to lichen planus. Furthermore, there may be deeper extension of the infiltrate, which is usually perivascular. There may also be mild exocytosis of lymphocytes.²⁹⁹ There is prominent melanin incontinence, and this is the only significant feature in older lesions. Subepidermal fibrosis was present in one case.³⁰⁸ The pigment usually extends deeper in the dermis than in postinflammatory pigmentation of other causes.²⁹⁷ Cases reported as lichen planus pigmentosus (discussed previously) have similar histological features.²⁹⁸

Immunofluorescence has shown IgM, IgG, and complement-containing colloid bodies in the dermis, as in lichen planus. There was a predominance of CD8⁺ lymphocytes in the dermis in one study.²⁷³ The exocytosing lymphocytes expressed cutaneous lymphocyte antigen (CLA).²⁷³ Apoptosis and residual filamentous bodies are present on electron microscopy.²⁵⁴ Another ultrastructural study showed irregular, immature melanosomes in keratinocytes and peripheral localization of melanosomes within keratinocytes.³⁰⁹

Differential diagnosis

The pigmentary incontinence seen in late-stage lesions is quite non-specific, showing overlap with *melasma*, third-stage *incontinentia pigmenti*, and numerous other conditions. Identifying traces of vacuolar alteration of the basilar layer or rare Civatte bodies can sometimes

Figure 3.8 Erythema dyschromicum perstans. (A) There is patchy basal cell damage and some pigment incontinence. (B) Another case of 'ashy dermatosis' that has almost 'burnt-out'. There is marked melanin incontinence. (H&E)

suggest the possibility of erythema dyschromicum perstans in preference to these other conditions, but often, clinical information is needed to secure a correct diagnosis.

Lichen planus actinicus

Lichen planus actinicus is a distinct clinical variant of lichen planus in which lesions are limited to sun-exposed areas of the body.^{310,311} It has a predilection for certain races,³¹² particularly young individuals of Oriental origin. There is some variability in the clinical expression of the disease in different countries, and this has contributed to the proliferation of terms used – lichen planus tropicus,³¹³ lichen planus subtropicus,³¹⁴ lichenoid melanodermitis,³¹⁵ and summertime actinic lichenoid eruption (SALE).^{311,316} Recently, it has been suggested that SALE is an actinic variant of lichen nitidus. The development of pigmentation in some cases³¹⁷ has also led to the suggestion that there is overlap with erythema dyschromicum perstans (discussed previously).²⁹¹ The pigmentation may take the form of melasma-like lesions.^{318,319} Such lesions have also been reported in childhood cases.⁷⁷ Lesions have been induced by repeated exposure to ultraviolet radiation.³²⁰

A rare erythematous variant has been described in a patient with chronic active hepatitis B infection.³²¹

Various treatments have been used, including hydroxychloroquine, intralesional corticosteroids combined with topical sunscreens, and retinoids. Oral cyclosporine has also been used.³²²

Histopathology³¹⁴

The appearances resemble lichen planus quite closely,³²³ although there is usually more marked melanin incontinence^{311,320} and there may be focal parakeratosis.³¹⁰ The inflammatory cell infiltrate in lichen planus actinicus is not always as heavy as it is in typical lesions of lichen planus.

Numerous immunoglobulin-coated cytooid bodies are usually present on direct immunofluorescence.³²⁴

Lichen planopilaris

Lichen planopilaris (follicular lichen planus) is a clinically heterogeneous variant of lichen planus in which keratotic follicular lesions are present, often in association with other manifestations of lichen planus.^{325–327} It typically affects middle-aged women and men. The annual incidence in four U.S. hair research centers varied from 1.15% to 7.59% of new cases, reflecting its relative rarity.³²⁸ The most common and important clinical group is characterized by scarring alopecia of the scalp, which is generalized in approximately half of these cases. The keratotic follicular lesions and associated erythema are best seen at the margins of the scarring alopecia.³²⁹ In this group, changes of lichen planus are present or develop subsequently in approximately 50% of cases.³²⁹ Rare cases have been reported in children.³³⁰

The **Graham Little-Piccardi-Lassueur syndrome** is a rare but closely related entity in which there is cicatricial alopecia of the scalp, follicular keratotic lesions of glabrous skin, and variable alopecia of the axillae and groins.^{327,331–333} It has been reported in a patient with androgen insensitivity syndrome (testicular feminization).³³⁴

Two other clinical groups occur, but they have not received as much attention.³²⁶ In one, there are follicular papules, without scarring, usually on the trunk and extremities. In the other, which is quite rare, there are plaques with follicular papules, usually in the retroauricular region, although other sites can be involved.³²⁶ This variant has been called *lichen planus follicularis tumidus*.³³⁵

Rare variants of lichen planopilaris include a linear form^{336–339} and the presence of lesions confined to the vulva.³⁴⁰ It has been reported in a patient with erythema dyschromicum perstans³⁴¹ and in another with scleroderma en coup de sabre.³⁴² It has developed in patients receiving etanercept³⁴³ or infliximab³⁴⁴ therapy. Lichen planopilaris has also been reported to follow hair transplantation or facelift surgery.³⁴⁵

Topical corticosteroid therapy (usually high-potency form) and intralesional steroids are the treatments of choice for patients with localized disease, particularly in the early phase.^{346,347} In one series of 30 cases treated with topical corticosteroids, resolution of the inflammatory process and blocking of the cicatricial progression were observed in 66% of cases.³⁴⁶ A mild reduction occurred in 20% of patients, and there was no response in 13%.³⁴⁶ Oral hydroxychloroquine is often used.³⁴⁸ Tetracyclines appear to be more effective than once thought.³⁴⁷ Cyclosporine was effective in a patient with the Graham Little-Piccardi-Lassueur syndrome.³³³ It has also been used in other forms of lichen planopilaris unresponsive to corticosteroids and hydroxychloroquine.³⁴⁸ Hair transplants and scalp reductions may be used in inactive end-stage disease.³⁴⁷

Histopathology^{325,326,329}

In lichen planopilaris, there is a lichenoid reaction pattern involving the basal layer of the follicular epithelium, with an associated dense

perifollicular infiltrate of lymphocytes and a few macrophages (Fig. 3.9). The changes involve the infundibulum and the isthmus of the follicle. One study reported that this is the so-called bulge region of the follicle where the stem cells reside.³⁴⁹ With regard to stem cells of the bulge region, all stem cell markers except for nestin are significantly reduced in lichen planopilaris; this is in contrast to alopecia areata, in which stem cell markers remain positive.³⁵⁰ It is the prototypical lymphocytic cicatricial alopecia.³⁰¹ The mean ratio of Langerhans cells to lymphocytes is higher for infiltrates in lichen planopilaris than for the those in long-standing traction alopecia.³⁵¹ Unlike lupus erythematosus, the infiltrate does not extend around blood vessels of the mid and deep plexus. There is also some mucin in the perifollicular fibroplasia, unlike lupus erythematosus, in which it is predominantly in the interfollicular dermis.³⁵² The interfollicular epidermis is involved in up to one-third of cases with scalp involvement^{326,329,353} and also in the rare plaque type (discussed previously). It is not usually involved in the variant with follicular papules on the trunk and extremities.³²⁶ If scarring alopecia develops, there is variable perifollicular fibrosis and loss of hair follicles that are replaced by linear tracts of fibrosis.³⁵³ There is also loss of the arrector pili muscles and sebaceous glands.³⁵² The papillary dermis may also be fibrosed. In advanced cases of scarring alopecia, the diagnostic features may no longer be present. The term 'pseudopelade' has been used by some for cases of end-stage scarring alopecia.

Direct immunofluorescence shows colloid bodies containing IgG and IgM in the dermis adjacent to the upper portion of the involved follicles.^{327,354} In one report, linear deposits of immunoglobulins were found along the basement membrane of the hair follicles (of the scalp) in all cases. Fibrin was present in one case; cytooid bodies were not demonstrated.³⁵⁵ Note that the lesions were of long standing (3–7 years).³⁵⁵

Differential diagnosis

Later stage lesions of lichen planopilaris with mainly perifollicular scarring, or those with milder or more loosely organized inflammatory infiltrates, can resemble other forms of scarring alopecia, including *central/centrifugal scarring alopecia*. However, the finding of dense, tightly packed inflammatory infiltrates around follicles, with vacuolar alteration of the basilar layer, strongly supports lichen planopilaris; identifying a lichenoid tissue reaction involving interfollicular epidermis, although uncommon, can further support the diagnosis. Lichen planopilaris and *discoïd lupus erythematosus* can also show similar follicular changes, but only lupus erythematosus would be expected to show perieccrine infiltrates, dermal mucin deposition, and frequent lipoatrophic changes, whereas lichen planopilaris is more apt to show a lack of interfollicular changes and a tightly packed, band-like lymphocytic infiltrate around the follicles.

Lichen planus pemphigoides

This rare disease is characterized by the coexistence of lichen planus and a heterogeneous group of subepidermal blistering diseases resembling bullous pemphigoid.^{356–358} There are tense bullae, often on the extremities, which may develop in normal or erythematous skin or in the lesions of lichen planus.^{359–362} They do not necessarily recur with subsequent exacerbations of the lichen planus.^{363,364} Oral lesions are exceedingly rare.³⁶⁵ Lichen planus pemphigoides has been reported in children.^{363,364,366} Rare clinical presentations include a unilateral distribution and onset following PUVA therapy.^{367,368} Similar lesions have been induced by the anti-motion sickness drug cinnarizine and by the ACE inhibitor ramipril.^{369–371} Other implicated agents include simvastatin, captopril, antituberculous medications, and a weight reduction drug.³⁷² Some cases have been reported in association with neoplasia, sharing this characteristic with paraneoplastic pemphigus.³⁷³

Figure 3.9 Lichen planopilaris. The lichenoid infiltrate is confined to a perifollicular location. Two different cases – (A) and (B). (H&E)

Lichen planus pemphigoides is different from **bullous lichen planus**,^{108,374} in which vesicles or bullae develop only in the lichenoid papules, probably as a result of unusually severe basal damage and accompanying dermal edema.^{375,376}

The pathogenesis of lichen planus pemphigoides appears to be due to epitope spreading. It has been suggested that damage to the basal layer in lichen planus may expose or release a basement membrane zone antigen, which leads to the formation of circulating antibodies and consequent blister formation.^{377–379} The target antigen is a novel epitope (MCW-4) within the C-terminal NC16A domain of the 180-kDa bullous pemphigoid antigen (BP180, type XVII collagen).^{380–382} There is a case report of a patient with subacute cutaneous lupus erythematosus who had lichenoid skin lesions and bullae; the target antigen in this case was the same as that previously described for lichen planus pemphigoides.³⁸³

Lichenoid erythrodermic bullous pemphigoid is a rare disease reported in African patients. It differs from lichen planus pemphigoides by the presence of a desquamative erythroderma and frequent mucosal lesions.³⁸⁴

Lichen planus pemphigoides may be treated with topical corticosteroids, systemic steroids, tetracycline and nicotinamide combined, retinoids, and dapsone.³⁸⁵ Systemic corticosteroids appear to be the most effective treatment for extensive disease.³⁸⁵

Histopathology

A typical lesion of lichen planus pemphigoides consists of a subepidermal bulla that is cell poor, with only a mild, perivascular infiltrate of lymphocytes, neutrophils, and eosinophils.³⁸⁶ The presence of neutrophils and eosinophils has not been mentioned in all reports. Sometimes a lichenoid infiltrate is present at the margins of the blister,³⁷⁵ and there are occasional degenerate keratinocytes in the epidermis overlying the blister.³⁵⁹ Lesions that arise in papules of lichen planus show predominantly the features of lichen planus; a few eosinophils and neutrophils are usually present, in contrast to bullous lichen planus in which they are absent.³⁵⁹ In one report, a pemphigus vulgaris-like pattern was present in the bullous areas.³⁸⁷

Direct immunofluorescence of the bullae will usually show IgG, C3, and C9 neoantigen in the basement membrane zone, and there is often a circulating antibody to the basement membrane zone.^{388,389} Indirect split-skin immunofluorescence has shown binding to the roof of the split.³⁷⁸

Electron microscopy

In lichen planus pemphigoides, the split occurs in the lamina lucida, as it does in bullous pemphigoid.^{378,390} Immunoelectron microscopy has shown that the localization of the immune deposits may resemble that seen in bullous pemphigoid, cicatricial pemphigoid, or epidermolysis bullosa acquisita – evidence of a heterogeneous disorder.³⁹¹

Keratosis lichenoides chronica

Keratosis lichenoides chronica is characterized by violaceous, papular, and nodular lesions in a linear and reticulate pattern on the extremities and a seborrheic dermatitis-like facial eruption.^{392–398} A rare vascular variant with telangiectasias has been reported.³⁹⁹ Oral ulceration and nail involvement may occur.^{400,401}

It is a rare condition, particularly in children.^{402–405} It has been suggested that pediatric-onset disease is different from adult-onset keratosis lichenoides chronica.⁴⁰⁶ Childhood cases may have familial occurrence and probably autosomal recessive inheritance. Early or congenital onset with facial erythematopurpuric macules is sometimes seen.⁴⁰⁶ Forehead, eyebrow, and eyelash alopecia are usually present. A case mimicking verrucous secondary syphilis has been reported.^{407,408} The condition is possibly an unusual chronic variant of

lichen planus, although this concept has been challenged.^{409,410} Böer believes that there is an authentic and distinctive condition that should continue to be called keratosis lichenoides chronica, but that many of the purported cases are lichen planus, lupus erythematosus, or lichen simplex chronicus.⁴¹¹

Keratosis lichenoides chronica may be associated with internal diseases such as glomerulonephritis, hypothyroidism, and lymphoproliferative disorders.^{399,409,412} In one patient with multiple myeloma, there were eruptive keratoacanthoma-like lesions.⁴¹³

The disease is refractory to many different treatment modalities,³⁹⁹ although calcipotriol or tacalcitol alone, or in combination with oral retinoids, may give good results.³⁹⁹ Oral retinoids alone are sometimes effective.⁴¹⁴ Phototherapy has also been used.⁴¹⁵

Histopathology

There is a lichenoid reaction pattern with prominent basal cell death and focal basal vacuolar change.⁴¹⁶ The inflammatory infiltrate usually includes a few plasma cells, and sometimes there is deeper perivascular and periappendageal cuffing.⁴¹⁷ Telangiectasia of superficial dermal vessels is sometimes noted.⁴¹⁸ Epidermal changes are variable, with alternating areas of atrophy and acanthosis sometimes present, as well as focal parakeratosis.⁴¹⁹ The parakeratosis often has a staggered appearance with neutrophil remnants.⁴¹¹ Cornoid lamellae and amyloid deposits in the papillary dermis have been recorded.⁴¹⁰ Numerous IgM-containing colloid bodies are usually found on direct immunofluorescence.⁴⁰⁰

The term ‘**lichen planoporiasis**’ was used for a case with the clinical features of keratosis lichenoides chronica and histological changes that included a lichenoid reaction centered on the acrosyringium and upper eccrine duct with focal squamous metaplasia of the upper duct and overlying hypergranulosis and keratin plugs.⁴²⁰ Ruben and LeBoit have also reported eccrine duct involvement in a case of keratosis lichenoides chronica.⁴²¹ Böer states that the lichenoid infiltrate in keratosis lichenoides chronica is commonly centered around infundibula and acrosyria.⁴¹¹

Differential diagnosis

Because of the infrequency of keratosis lichenoides chronica, it can potentially be confused with other lichenoid dermatoses. However, it does not generally show the classic features of *lichen planus*, and the parakeratosis, the variable atrophy and acanthosis seen in some lesions, and the deeper dermal perivascular and periadnexal infiltrates are reasonably distinctive. See later for the distinction from lichen striatus.

Lupus erythematosus–lichen planus overlap syndrome

Lupus erythematosus–lichen planus overlap syndrome is a heterogeneous entity in which one or more of the clinical, histological, and immunopathological features of both diseases are present.^{422,423} Some cases may represent the coexistence of lichen planus and lupus erythematosus, whereas in others the ultimate diagnosis may depend on the course of the disease.^{424,425} In most cases, the lupus erythematosus is of the chronic discoid or systemic type; rarely, it is of the subacute type.⁴²⁶ It was the cause of a scarring alopecia in one case.⁴²⁷ Before the diagnosis of an overlap syndrome is entertained, it should be remembered that some lesions of cutaneous lupus erythematosus may have numerous Civatte bodies and a rather superficial inflammatory cell infiltrate that at first glance may be mistaken for lichen planus. The use of an immunofluorescent technique using a patient's serum and autologous lesional skin as a substrate may assist in the future in elucidating the correct diagnosis in some of these cases.⁴²⁸

LICHEN NITIDUS

Lichen nitidus is a rare, usually asymptomatic chronic eruption characterized by the presence of multiple, small flesh-colored papules, 1 or 2 mm in diameter.^{429,430} The lesions have a predilection for the upper extremities, chest, abdomen, and genitalia of children and young adult males.^{429,431} The disorder is most often localized, but sometimes lesions are more generalized.^{432–434} Familial cases are rare.⁴³⁵ It has been reported in association with Down syndrome^{436,437} and the Russell–Silver syndrome.⁴³⁸ Nail changes^{439,440} and involvement of the palms and soles^{441–443} have been reported. It has been suggested that cases reported in the past as SALE should be reclassified as actinic lichen nitidus.^{444–446} It has been reported in association with lichen spinulosus.⁴⁴⁷

Although regarded originally as a variant of lichen planus, lichen nitidus is now considered a distinct entity of unknown etiology. It has followed hepatitis B vaccination.⁴⁴⁸ The lymphocytes in the dermal infiltrate in lichen nitidus express different markers from those in lichen planus.⁴⁴⁹ Lichen planus has developed subsequent to generalized lichen nitidus in a child.⁴⁵⁰

Although spontaneous remissions of lichen nitidus are common,⁴³² persistent lesions and those that are refractory to various treatments can pose therapeutic challenges. Sometimes resolution is accompanied by postinflammatory hyperpigmentation.⁴³² Some of the treatments used include systemic and topical corticosteroids, antihistamines, retinoids, low-dose cyclosporine, itraconazole, isoniazid, and ultraviolet therapy.^{433,451} Generalized lichen nitidus has been successfully treated with narrowband-UVB phototherapy.^{433,452}

Histopathology

A papule of lichen nitidus shows a dense, well-circumscribed, subepidermal infiltrate, sharply limited to one or two adjacent dermal papillae.⁴²⁹ Claw-like, acanthotic rete ridges, which appear to grasp the infiltrate, are present at the periphery of the papule (Fig. 3.10). The inflammatory cells push against the undersurface of the epidermis, which may be thinned and show overlying parakeratosis. Occasional Civatte bodies are present in the basal layer.

In addition to lymphocytes, histiocytes, and melanophages, there are also epithelioid cells and occasional multinucleate giant cells in the inflammatory infiltrate.⁴⁵³ Rarely, plasma cells are conspicuous.⁴⁵⁴ A spinous follicular variant of lichen nitidus, first described by Madhok and Winkelmann, shows perifollicular granulomas.⁴⁵⁵ The infiltrates of lichen nitidus include both CD68⁺ macrophages and S100⁺, CD1a⁺ Langerhans cells.⁴⁵⁶ Rare changes that have been reported include subepidermal vesiculation,⁴⁵⁷ transepidermal elimination of the inflammatory infiltrate,^{453,458,459} and the presence of perifollicular granulomas.⁴⁶⁰ Periappendageal inflammation mimicking lichen striatus has also been reported.⁴⁶¹

Direct immunofluorescence is usually negative, a distinguishing feature from lichen planus.

Electron microscopy

The ultrastructural changes in lichen nitidus are similar to those of lichen planus.⁴⁶²

Differential diagnosis

Lichen nitidus can resemble the smaller papular lesions of *lichen planus* that only involve several dermal papillae. Occasionally, one encounters other lesions, such as *arthropod reactions*, that are characterized by discrete, superficial dermal infiltrates, but in most instances these lesions either lack the classic features of lichen nitidus (vacuolar alteration of the overlying basilar layer, confinement to a single dermal

Figure 3.10 Lichen nitidus. (A) There are two discrete foci of inflammation involving the superficial dermis. (B) Claw-like downgrowths of the rete ridges are present at the margins of these foci. (C) Another case with a broader lesion. (H&E)

papilla, and 'ball in claw' configuration) or show more widely distributed inflammation with different cellular components. It should also be recognized that the diagnostic changes can easily be absent in a given tissue section; therefore, serial sections may then be necessary to find these tiny lesions. The appearances are sometimes frankly

granulomatous, and these lesions must therefore be distinguished from disseminated granuloma annulare in which the infiltrate may be superficial and the necrobiosis sometimes quite subtle. Uncommon examples with transepidermal elimination might also be confused with perforating granuloma annulare or possibly with reactive perforating collagenosis, although the latter lacks the characteristic inflammatory changes. Lichen nitidus also needs to be distinguished from an early lesion of lichen scrofulosorum. Whereas the infiltrate in lichen nitidus ‘hugs’ the epidermis and expands the dermal papilla, the granulomas in lichen scrofulosorum do not cause widening of the papillae. Furthermore, in lichen scrofulosorum there may be mild spongiosis and exocytosis of neutrophils into the epidermis.⁴⁶³

LICHEN STRIATUS

Lichen striatus is a linear, papular eruption of unknown etiology that may extend in a continuous or interrupted manner along one side of the body, usually the length of an extremity.^{464,465} Annular⁴⁶⁶ and bilateral forms⁴⁶⁷ have been reported. The lesions often follow Blaschko’s lines,^{468–471} this is almost invariable for lesions on the trunk and face.⁴⁷² Nail changes are not uncommon,^{473,474} resulting in onychodystrophy.⁴⁷⁵ Lichen striatus has a predilection for female children and adolescents.⁴⁷² Familial cases are rare.⁴⁷⁶ An unusual presentation in children is the presence of linear lesions on the nose with some overlap features with lupus erythematosus.⁴⁷⁷ Spontaneous resolution usually occurs after 6 months, although some cases persist longer.⁴⁷² Hypochromic sequelae occur in nearly 30% of cases; hyperchromic sequelae are much less common.⁴⁷² Relapses are uncommon. A history of atopy is sometimes present in affected individuals.^{472,478}

Lichen striatus has been reported following BCG vaccination,⁴⁷¹ varicella infection,⁴⁷⁹ solarium exposure,⁴⁸⁰ and following a flu-like illness.⁴⁸¹ It has also developed in a pregnant woman⁴⁸² and in a patient with plaque psoriasis.⁴⁸³ It has been suggested that lichen striatus represents an autoimmune CD8-mediated response against a mutated keratinocytic clone, which represents a somatic mutation occurring after fertilization.⁴⁷²

Because lichen striatus usually resolves spontaneously, therapy is not required.⁴⁷³ Topical steroids have been used to treat the disease, but they do not appear to influence the duration of the lesions.⁴⁷² Tacrolimus (0.1%) is an effective treatment option for lichen striatus of the face and other areas.^{484–486} Pimecrolimus cream has also been effective in adult patients.^{487–489}

Histopathology^{464,490–492}

There is a lichenoid reaction pattern with an infiltrate of lymphocytes, histiocytes, and melanophages occupying three or four adjacent dermal papillae.⁴⁹² The overlying epidermis is acanthotic with mild spongiosis associated with exocytosis of inflammatory cells. Small intraepidermal vesicles containing Langerhans cells are present in half of the cases.⁴⁹³ Dyskeratotic cells are often present at all levels of the epidermis; such cells are uncommon in linear lichen planus.⁴⁹⁴ There is usually mild hyperkeratosis and focal parakeratosis.⁴⁶⁴ The dermal papillae are mildly edematous. The infiltrate is usually less dense than in lichen planus, and it may extend around hair follicles or vessels in the mid-plexus. Eccrine extension of the infiltrate is often present (Fig. 3.11).^{490,491} A monoclonal population of T cells has been reported in one case but excluded in others.⁴⁹⁵

Electron microscopy

Dyskeratotic cells similar to the corps ronds of Darier’s disease have been described in the upper epidermis.⁴⁹¹ The Civatte bodies in the basal layer show the usual changes of apoptosis on electron microscopy.

Figure 3.11 Lichen striatus. This case has a flord perieccrine infiltrate of lymphocytes. (H&E)

Differential diagnosis

It should not be forgotten that lichen striatus has been called a ‘chameleon’.⁴⁹³ The histology may closely mimic lichen nitidus or lichen planus even though the clinical features are those of lichen striatus. Furthermore, adult blaschkitis may have histological features that overlap with lichen striatus.⁴⁹⁶ However, blaschkitis is said to have features of spongiotic dermatitis, in contrast to lichen striatus, which despite some mild spongiosis is predominantly lichenoid and often features a more deeply extending dermal infiltrate.⁴⁹⁷ The biopsy changes are usually not confused with lichen planus, because the epidermal changes are dissimilar, and the deeper, perieccrine infiltrates are not seen in lichen planus. The findings are also similar to those in keratosis lichenoides chronica, particularly in terms of the perieccrine infiltration, but the latter lesion is more likely to show epidermal acanthosis, or variable acanthosis and atrophy. Because lichen striatus is linear, it has clinical resemblances to inflammatory linear verrucous epidermal nevus, other epidermal nevi, or linear lichen planus or psoriasis. However, all of those lesions show acanthosis and often degrees of papillomatosis, which are not features of lichen striatus.

Figure 3.12 (A) Lichen planus-like keratosis. (B) There is a lichenoid reaction pattern with some deeper extension of the infiltrate than is usual in lichen planus. (H&E)

LICHEN PLANUS-LIKE KERATOSIS (BENIGN LICHENOID KERATOSIS)

Lichen planus-like keratosis (LPLK) is a commonly encountered entity in routine histopathology.⁴⁹⁸⁻⁵⁰⁴ Synonyms used for this entity include solitary lichen planus, benign lichenoid keratosis,⁴⁹⁹ lichenoid benign keratosis,^{500,501} and involuting lichenoid plaque.⁵⁰² It should not be confused with lichenoid actinic (solar) keratosis,⁵⁰⁵ in which epithelial atypia is a prerequisite for diagnosis.⁵⁰⁶ Lichen planus-like keratoses are usually solitary, discrete, slightly raised lesions of short duration, measuring 3–10 mm in diameter. Multiple lesions (20–40) have been reported, but the illustration of one such case appears to show a cornoid lamella.⁵⁰⁷ In a study of 1040 cases, 8% of patients presented with two lesions, and less than 1% presented with three lesions.⁵⁰⁸ The sudden appearance of the lesion is often a striking feature. Lesions are violaceous or pink, often with a rusty tinge.⁴⁹⁸ There may be a thin, overlying scale. The dermoscopic features correlate with the stage of the lesion and the nature of the lesion being regressed.^{509,510} There is a predilection for the arms and presternal area of middle-aged and elderly women.⁵⁰⁸ Lesions are sometimes mildly pruritic or 'burning'.⁴⁹⁹ Clinically, LPLK is usually misdiagnosed as a basal cell carcinoma or Bowen's disease.

Lichen planus-like keratosis is a heterogeneous condition that usually represents the attempted cell-mediated immune rejection of any of several different types of epidermal lesion. In most instances, this is a solar lentigo,^{498,511,512} but in some lesions there is a suggestion of an underlying seborrheic keratosis, large cell acanthoma, or even a viral wart.⁵¹³ Constant pressure was incriminated in one case.⁵¹⁴ Acetaminophen (paracetamol) was incriminated in another case.⁵¹⁵ In one study, a contiguous solar lentigo was present in only 7% of cases and a seborrheic keratosis in 8.4%.⁵⁰³ These findings do not accord with the author's own experiences, and in fact, recent screening of lichen planus-like keratoses for selected mutations showed FGFR3, PIK3CA, and RAS mutations in approximately half of the study cases, supporting the concept that many of these lesions represent regressive variants of epidermal tumors such as solar lentigines and seborrheic keratoses.⁵¹⁶

Histopathology^{500,501,512}

There is a florid lichenoid reaction pattern with numerous apoptotic keratinocytes in the basal layer and accompanying mild vacuolar change (Fig. 3.12). The infiltrate is usually quite dense and often includes a few

Figure 3.13 Lichen planus-like keratosis. It is arising in a large cell acanthoma. (H&E)

plasma cells, eosinophils, and even neutrophils in addition to the lymphocytes and macrophages. The infiltrate may obscure the dermoepidermal interface. A rare variant of LPLK has histological features simulating mycosis fungoides.⁵¹⁷ Pautrier-like microabscesses, the alignment of lymphocytes along the basal layer, and epidermotropism are features of this variant.⁵¹⁷ Some of the cells are CD30+.⁵⁰⁸

Pigment incontinence may be prominent. This is so in the late (regressed, atrophic) stage; epidermal atrophy and papillary dermal fibrosis are also present.⁵⁰⁸ There may be mild atypia of keratinocytes, but this is never as marked as it is in a lichenoid solar keratosis.³⁵ Before a diagnosis of LPLK is made, the sections should be carefully scanned to ensure that there is not an underlying melanocytic proliferation.⁵¹⁸

There is often mild hyperkeratosis and focal parakeratosis.⁵⁰³ The presence of parakeratosis allows a distinction to be made with lichen planus. Hypergranulosis is not as pronounced as in lichen planus. A contiguous solar lentigo or large cell acanthoma (Fig. 3.13) is sometimes seen.⁵¹⁹

Usually, cell death is scattered and of apoptotic type. At times, confluent necrosis occurs, and in these cases lichenoid subepidermal clefting may

Figure 3.14 Lichen planus-like keratosis of the toxic epidermal necrolysis type. (A) There is blister formation in this region. (B) Another area of the same case. (H&E)

result. Sometimes this variant simulates toxic epidermal necrolysis (Fig. 3.14). At other times, the lesions are bullous with a heavy lymphocytic infiltrate and increased numbers of dead basal keratinocytes.⁵⁰⁸ There is also a rare ‘creeping’ form in which there is focal acute activity and other areas with few lymphocytes, little if any apoptotic cell death, and some melanin incontinence. A careful search for a cornoid lamella of porokeratosis should always be made when these changes are present.

The attempt to classify ‘lichenoid keratoses’ into three groups – lichen planus-like keratosis, seborrheic keratosis-like lichenoid keratosis, and lupus erythematosus-like lichenoid keratosis – deserves some comment.⁵²⁰ The seborrheic keratosis-like variant is best called an irritated (lichenoid) seborrheic keratosis, and the lupus erythematosus-like variant is simply a lesion with some basal clefting (discussed previously). It may sometimes represent early lupus erythematosus.⁵²¹ Notwithstanding this comment, the author admits that making a distinction between LPLK and lupus erythematosus is occasionally difficult for lesions on the face in which the biopsy is small. The presence of follicular involvement in lupus erythematosus and its absence in

Table 3.4 Histological types of lichen planus-like keratosis (benign lichenoid keratosis) ^a
Classic
Atrophic
Atypical (mycosis fungoides-like)
Bullous
TEN-like
‘Creeping’
Lupus simulant

^aThe early/interface variant is more likely to be a reflection of the underlying lesion undergoing regression rather than a variant *sui generis*.

LPLK is not a reliable point of distinction because some LPLKs can have not only involvement of the infundibula of follicles but also follicular involvement at a slightly deeper level.

A summary of the histological types of LPLK is shown in Table 3.4. Direct immunofluorescence shows colloid bodies containing IgM and some basement membrane fibrin.⁵⁰⁰ Immunohistochemistry shows fewer Langerhans cells in the epidermis than in lichen planus.⁵²² The infiltrate is polyclonal.⁵²³

Mention should be made of the report of Melan A-positive pseudonests in the setting of lichenoid inflammation.⁵²⁴ These nests did not stain for S100 protein or a ‘melanoma cocktail’.⁵²⁴ A subsequent paper found no Melan A/MART-1-positive pseudonests in lichenoid inflammation.⁵²⁵ A recent study found that 4 of 70 cases of lichenoid keratoses contained an occasional MART-1-positive nest; in each case, staining for microphthalmia transcription factor (Mitf) was also positive, confirming that these structures were indeed melanocytic nests.⁵²⁶

Shave excision is the usual method of treatment for these lesions.

Differential diagnosis

With regard to the features usually mentioned as differentiating points between lichenoid keratosis and *lichen planus*, eosinophils can sometimes be seen in true lichen planus. This is particularly encountered in rapidly evolving, widespread disease. However, in general, plasma cells in cutaneous lesions of lichen planus are uncommon, and their finding can be useful in pointing toward another lichenoid lesion such as lichen planus-like keratosis. *Lichenoid actinic keratosis* bears a definite resemblance to benign lichenoid keratosis, but there is a greater degree of basilar keratinocyte atypia, often extending laterally from the zone of most intense dermal inflammation. *Lichenoid drug eruption* shows many of the same microscopic features as lichenoid keratosis, so a distinction may depend on clinical information. A solitary lesion in a typical location obviously favors lichenoid keratosis, but in situations in which there are several lesions, differentiation may be more difficult. Finding changes of solar lentigo or seborrheic keratosis in a biopsy also supports the diagnosis of lichenoid keratosis.

LICHENOID DRUG ERUPTIONS

A lichenoid eruption has been reported following the ingestion of a wide range of chemical substances and drugs.^{527,528} The eruption may closely mimic lichen planus clinically, although at other times there is eczematization and more pronounced, residual hyperpigmentation. Rarely, the eruption follows Blaschko’s lines.⁵²⁹ Some of the β -adrenergic blocking agents produce a psoriasiform pattern clinically but lichenoid features histologically.^{530,531} Discontinuation of the drug usually leads to clearing of the rash over a period of several weeks.⁵³² A lichenoid reaction has developed in a temporary henna tattoo,⁵³³ as well as in permanent tattoos.^{534,535}

Lichenoid eruptions have been produced by gold,⁵³⁶ gold-containing liquor,^{537,538} methyldopa,⁵³⁹ β -adrenergic blocking agents,⁵⁴⁰ penicillamine,⁵⁴¹ quinine,⁵⁴² quinidine,⁵⁴³ synthetic antimalarials,⁵⁴⁴ and ethambutol.⁵⁴⁵ Less common causes of a lichenoid reaction are captopril,⁵⁴⁶ enalapril,^{547,548} amlodipine,⁵⁴⁹ naproxen,^{550–552} dapsone, simvastatin,⁵⁵³ pravastatin,⁵⁵⁴ indapamide, arsenicals, mercury,⁵⁵⁵ iodides, imatinib,^{556,557} etanercept,⁵⁵⁸ adalimumab,⁵⁵⁹ infliximab,⁵⁶⁰ acetylsalicylic acid,⁵⁶¹ orlistat,⁵⁶² ticlopidine,⁵⁶³ sodium valproate,⁵⁶⁴ nicorandil,⁵⁶⁵ terazosin,⁵⁶⁶ carbamazepine,⁵⁶⁷ phenothiazine derivatives, salsalate,⁵⁶⁸ chlorpropamide,⁵⁶⁹ suramin,⁵⁷⁰ tiopronin,⁵⁷¹ docetaxel,⁵⁷² dactinomycin,⁵⁷³ doxorubicin,^{574–577} cyanamide,⁵⁷⁸ omeprazole, lansoprazole, pantoprazole,⁵⁷⁹ spironolactone,⁵⁸⁰ metformin,⁵⁸¹ glimepiride,⁵⁸² indoramin,⁵⁸³ IFN- α -2b, intravenous immunoglobulin,⁵⁸⁴ streptomycin,⁵⁸⁵ alendronate,⁵⁸⁶ and zidovudine.⁵⁸⁷ *Photodistributed lesions* may occur with thiazides, some tetracyclines,⁵⁸⁹ sparflaxacin,⁵⁹⁰ nimesulide,⁵⁹¹ torsemide (a loop diuretic),⁵⁹² clopidogrel,⁵⁹³ solifenacin,⁵⁹⁴ capecitabine,⁵⁹⁵ diltiazem,^{596–598} ethambutol,¹⁷³ quinine,¹⁷³ pyritinol,¹⁷³ carbamazepine,¹⁷³ pyrazinamide,⁵⁹⁹ and docetaxel.⁶⁰⁰ Hyperpigmentation may follow.⁵⁹⁸ A lichenoid stomatitis, which may take time to clear after cessation of the drug, can be produced by methyldopa and rarely by lithium carbonate⁶⁰¹ or propranolol. Contact with color film developer may produce a lichenoid photodermatitis.⁵³² A topical mixture of the local anesthetic agents lidocaine and prilocaine produced basal clefting similar to epidermolysis bullosa simplex with basophilic granules in the cleft.^{602,603} A lichen planus-like eruption has been reported at sites repeatedly exposed to methacrylic acid esters used in the car industry⁶⁰⁴ and also at injection sites of granulocyte colony-stimulating factor (G-CSF).⁶⁰⁵ A severe lichenoid eruption and stomatitis developed in a patient receiving G-CSF, IFN- α -2a, and ribavirin.⁶⁰⁶ Voriconazole has induced a blistering eruption with histological lichenoid features. The eruption occurred in the setting of graft-versus-host disease.⁶⁰⁷ A list of the drugs that produce lichenoid eruptions is included in **Table 3.5**.

Histopathology^{532,608}

Lichenoid drug eruptions usually differ from lichen planus by the presence of focal parakeratosis and mild basal vacuolar change, as well as a few eosinophils and sometimes plasma cells in the infiltrate (**Fig. 3.15**). These features are said to be more common in non-photodistributed lesions, whereas photodistributed lesions may mimic lichen planus.⁶⁰⁹ Apoptotic keratinocytes may be found above the basal layer in lichenoid drug reactions, an uncommon feature in lichen planus.⁶¹⁰ There is often more melanin incontinence than in lichen planus. The infiltrate is often less dense and less band-like than in lichen planus itself. A few inflammatory cells may extend around vessels in the mid and lower dermis. Sometimes the histological features closely simulate those of lichen planus.⁶⁰⁹ A few eosinophils in the infiltrate may be the only clue to the diagnosis.

An unusual lichenoid reaction with epidermotropic multinucleate giant cells in the inflammatory infiltrate has been reported in patients taking a variety of drugs.⁶¹¹ The term '**giant cell lichenoid dermatitis**' has been used for this pattern (**Fig. 3.16**).⁶¹² One patient subsequently developed sarcoidosis.⁶¹² '**Lichenoid sarcoidosis**' has been used for a case with both lichenoid and sarcoidal features.⁶¹³ Giant cell lichenoid dermatitis has been reported in herpes zoster scars, particularly in bone marrow recipients.⁶¹⁴ A giant cell lichenoid dermatitis was present in a patient with baboon syndrome (see p. 129). It followed the intravenous administration of amoxicillin-clavulanic acid.⁶¹⁵

FIXED DRUG ERUPTIONS

A fixed drug eruption is a round or oval erythematous lesion that develops within hours of taking the offending drug and that recurs at the same site with subsequent exposure to the drug.⁶¹⁶ Lesions may be solitary or multiple. A bullous variant with widespread lesions also

Table 3.5 Drugs producing a lichenoid (interface) pattern (but excluding cases with only rare apoptotic keratinocytes)

Lichen planus pemphigoides: cinnarizine, ramipril

Lichenoid drug eruption: acetylsalicylic acid, adalimumab, alendronate, amlodipine, antimalarials, arsenicals, β -blockers, captopril, carbamazepine, chlorpropamide, cyanamide, dactinomycin, dapsone, docetaxel, doxorubicin, enalapril, etanercept, ethambutol, glimepiride, gold, granulocyte colony-stimulating factor (local), hepatitis B vaccination, imatinib, indapamide, indoramin, infliximab, interferon- α -2b, intravenous immunoglobulins, iodides, lansoprazole, mercury, metformin, methyldopa, naproxen, nicorandil, omeprazole, orlistat, pantoprazole, penicillamine, phenothiazine, pravastatin, quinidine, quinine, salsalate, simvastatin, spironolactone, streptomycin, suramin, terazosin, ticlopidine, tiopronin, valproic acid, zidovudine

Photolichenoid drug eruption: clopidogrel, docetaxel, nimesulide, pyrazinamide, solifenacin, sparflaxacin, tetracyclines, thiazides, torsemide

Fixed drug eruption: acetaminophen (paracetamol), acetaminophen/indomethacin/granisetron/IL-2 combination, acetylsalicylic acid, amoxicillin, amlodipine, antimalarials, antituberculous drugs, carbamazepine, celecoxib, cetirizine, chlormezanone, ciprofloxacin, clarithromycin, clioquinol, colchicine, cotrimoxazole, dextromethorphan, diltiazem, dimenhydrinate, diphenhydramine, enalapril, eperisone hydrochloride, erythromycin, esomeprazole, etodolac, etoricoxib, feprazole, fluconazole, fluoxetine, griseofulvin, ibuprofen, influenza vaccine, interferon- β , iodinated contrast media, iomeprol, itraconazole, kakkonto (herbal drug), ketoconazole, lactose, lamotrigine, lansoprazole, levocetirizine, levofloxacin, loopromide, mefenamic acid, mesna (cyclophosphamide and ifosfamide), metamizole, metronidazole, minocycline, naproxen, nimesulide, noscapine, nystatin, omeprazole, ornidazole, paclitaxel, pazufloxacin, penicillin, pethidine, phenolphthalein, phenylbutazone, phenylpropanolamine hydrochloride, phenytoin, piroxicam, promethazine, pseudoephedrine, quinine, rifampicin, rupatadine, S-carboxymethyl-L-cysteine, sorafenib, sulfamethoxazole, sulfonamides, tartrazene, temazepam, tenoxicam, terbinafine, tetracyclines, theophylline, ticlopidine, tinidazole, tiopidine, topotecan, tranexamic acid, tranquilizers, trimethoprim, tropisetron, vancomycin

Erythema multiforme/TEN: acarbose, acetaminophen (paracetamol), alfuzosin, allopurinol, amifostine, aminopenicillins, amphetamines, ampicillin/sulbactam, bezafibrate, bupropion, carbamazepine, ceftazidime, chloroquine, cimetidine, ciprofloxacin, citalopram, clarithromycin, clindamycin, clobazam, clonazepam, cocaine, colchicine, corticosteroids, cyclophosphamide, cytosine arabinoside, diacerein, doxycycline, escitalopram, ethambutol, etretinate, famotidine, fenoterol, fluoxetine, fluvoxamine, gemeprost, griseofulvin, hydroxychloroquine, imatinib, indapamide, indomethacin, iopentol, irbesartan, isoniazid, isoxicam, lamotrigine, lansoprazole, latanoprost eye drops, leflunomide, mefloquine, methotrexate, mifepristone, moxifloxacin, nevirapine, nitrogen mustard, nystatin, ofloxacin, oxaprozin, oxazepam, pantoprazole, paroxetine, phenylbutazone, phenytoin, piroxicam, pravastatin (photosensitivity), progesterone, pseudoephedrine, ramipril, ranitidine, ritodrine, rituximab, rofecoxib, sennoside, sertraline, simvastatin (photosensitivity), sorafenib, sulfamethoxazole, suramin, telithromycin, terbinafine, tetrazepam, thalidomide, theophylline, thiacezone, ticlopidine, tramadol, trichloroethylene, trimethoprim, valdecoxib, valproic acid, vancomycin, voriconazole, zonisamide

Subacute lupus erythematosus: adalimumab, anastrozole, antihistamines, bupropion, calcium channel blockers, capecitabine, captopril, cilazapril, cinnarizine, citalopram, diltiazem, doxorubicin, doxycycline, efalizumab, esomeprazole, etanercept, fluorouracil, griseofulvin, golimumab, imiquamod (topical), infliximab, lansoprazole, leflunomide, naproxen, nifedipine, omeperazole, oxyphenolol, phenytoin, piroxicam, radioiodine, ranitidine, simvastatin, terbinafine, thiazides, ticlopidine, tiotropium, verapamil

Systemic lupus erythematosus: allopurinol, atenolol, captopril, carbamazepine, chlorpromazine, clonidine, danazol, etanercept, ethosuximide, griseofulvin, hydralazine, hydrochlorothiazide, isoniazid, lithium, lovastatin, mesalazine, methimazole, methyldopa, minocycline, penicillin, penicillamine, phenobarbital, phenylbutazone, phenytoin, piroxicam, practolol, primidone, procainamide, propylthiouracil, quinidine, rifampicin, streptomycin, sulfonamides, terbinafine, tetracycline derivatives, thiamazole, trimethadione, valproate

Figure 3.15 Lichenoid drug eruption. There is focal parakeratosis and a few eosinophils in the infiltrate. Early changes of photosensitivity are apparent. (H&E)

Figure 3.16 Giant cell lichenoid dermatitis. There are several multinucleate giant cells in the lichenoid infiltrate. (H&E)

occurs.⁶¹⁷⁻⁶¹⁹ Fixed eruptions subside on withdrawal of the drug, leaving a hyperpigmented macule.⁶²⁰ Nonpigmenting lesions have been described,⁶²¹⁻⁶²³ and depigmented areas may be the result in patients whose skin is naturally heavily pigmented. Sometimes there is a burning sensation in the erythematous lesions, but systemic manifestations such as malaise and fever are uncommon.⁶¹⁶ Rare clinical variants include eczematous, necrotizing,⁶²⁴ cellulitis-like,⁶²⁵ 'Dalmatian dog'-like,⁶²⁶ urticarial, linear,^{627,628} 'wandering',⁶²⁹ butterfly rash-like,⁶³⁰ and erythema dyschromicum perstans-like⁶³¹ types. A unilateral eruption of the breast has been reported.⁶³² In two cases, the eruption occurred at the sites of ear piercing.⁶³³ An interesting presentation concerns the fixed drug eruption that developed in a male after coitus, which was thought to have resulted from the trimethoprim-sulfamethoxazole that his wife was taking.⁶³⁴ Other 'sexually transmitted' cases have since been reported.⁶³⁵ Common sites of involvement include the face, lips,⁶³⁶ buttocks, and genitals.^{637,638} Paronychia is a rare presentation.⁶³⁹

In one series of 446 cases of drug eruption, 92 (21%) were instances of fixed drug eruptions, and of these, 16 were bullous and generalized.⁶⁴⁰ More than 100 drugs have been incriminated, but the major offenders are sulfonamides,⁶⁴¹ particularly the combination of trimethoprim-sulfamethoxazole,^{634,642,643} tetracyclines,⁶⁴³⁻⁶⁴⁵ tranquilizers, quinine, phenolphthalein (in laxatives), and some analgesics.^{646,647}

In some countries, antituberculous drugs and antimalarials are a major cause of a fixed drug eruption.⁶⁴⁸ Specific drugs incriminated in the literature include minocycline,⁶⁴⁵ nystatin,⁶⁴⁹ colchicine,⁶⁵⁰ clioquinol,⁶⁵¹ penicillin,⁶⁵² amoxicillin,⁶⁵³ erythromycin,⁶⁵⁴ clarithromycin,⁶⁵⁵ ciprofloxacin,⁶⁵⁶ vancomycin,⁶⁵⁷ rifampicin,⁶⁴⁷ tranexamic acid,⁶⁵⁸ griseofulvin,⁶⁵⁹ terbinafine,⁶⁶⁰ dimenhydrinate (Gravol®),⁶⁶¹⁻⁶⁶³ diphenhydramine,⁶⁶⁴ levocetirizine,⁶⁶⁵ paclitaxel,⁶⁶⁶ topotecan,⁶⁶⁵ temazepam,⁶⁶⁷ mefenamic acid,^{618,626,668} carbamazepine,^{669,670} acetylsalicylic acid,⁶⁷¹ acetaminophen (paracetamol),⁶⁷¹⁻⁶⁷⁹ fluconazole,^{680,681} ketoconazole,⁶⁸² itraconazole,⁶⁸² feprazone,⁶⁸³ tartrazine,⁶⁸⁴ ticlopidine,⁶⁸⁵ phenytoin,⁶⁷⁰ lamotrigine,⁶⁸⁶ pseudoephedrine,^{687,688} dextromethorphan,⁶⁸⁹ iomeprol,⁶⁹⁰ phenylpropanolamine hydrochloride,⁶⁹¹ tropisetron,⁶⁹² metramizole,⁶⁴⁴ phenylbutazone,⁶⁴⁴ etodolac,⁶⁹³ metamizole,⁶⁹⁴ naproxen,^{632,695,696} piroxicam,^{633,697} tenoxicam,⁶³³ IFN- β -1b,⁶⁹⁸ ibuprofen,⁶⁹⁹ acetaminophen/indomethacin/granisetron/IL-2 in combination,⁷⁰⁰ celecoxib,⁶⁴⁷ chlorzoxanone,⁶⁴⁷ omeprazole,⁶⁷¹ diltiazem,⁶⁷¹ enalapril,⁶⁷¹ lansoprazole,⁶⁷¹ fluoxetine,⁶⁷¹ amlopidine,⁶⁷¹ S-carboxymethyl-L-cysteine,⁷⁰¹ eperisone hydrochloride,⁷⁰² lactose,^{703,704} metronidazole,⁷⁰⁵⁻⁷⁰⁷ tinidazole,⁷⁰⁵ nimesulide,⁷⁰⁸ cetirizine,^{709,710} and theophylline.⁶³¹ More complete lists are included in several reviews of the subject.^{616,646,647}

The drugs responsible are listed in Table 3.5. Two different drugs have been involved in the same patient.^{711,712} In yet another report, three different drugs each produced a fixed drug eruption at a different site.⁷¹³ In situations in which more than one drug has produced a fixed eruption, the agents are not necessarily structurally related.⁷¹⁴ It has been suggested that the distribution of lesions is influenced by the drug in question; tetracyclines and cotrimoxazole tend to involve the glans penis, whereas pyrazolones and naproxen affect mainly the lips and mucosae.^{642,715} Antimalarials mainly involve the face and lips.⁶⁴⁸ There are rare reports of **fixed food eruptions**. Lentils⁷¹⁶ and strawberries⁷¹⁷ have been implicated. Foods may sometimes produce a flare in a fixed drug eruption.⁷¹⁸

The Japanese herbal drug 'kakkon-to' has produced an extensive fixed drug eruption.⁷¹⁹ A solitary lesion has been produced by the Chinese herbal medicine ma huang (Herba Ephedrae), mainly containing pseudoephedrine and ephedrine.⁷²⁰ Influenza vaccination has resulted in a generalized bullous eruption.⁶¹⁹ In some instances, no agent can be incriminated. Such cases have been called '*fixed drug-like eruption*'.⁷²¹

Numerous studies have attempted to elucidate the pathogenesis of fixed eruptions. It appears that the offending drug acts as a hapten and binds to a protein in basal keratinocytes and sometimes melanocytes.⁶¹⁶ As a consequence, an immunological reaction is stimulated, which probably takes the form of an antibody-dependent, cellular

cytotoxic response.⁷²² CD8⁺ T lymphocytes attack the drug-altered epidermal cells, producing apoptosis; it appears to be mediated by Fas ligand (FasL), in the presence of IFN- γ , triggering a caspase cascade.^{155,723} Drug-specific CD8⁺ memory T cells also play a role in preserving the cutaneous memory function that characterizes a fixed eruption.^{633,724} It appears that these memory T cells transiently acquire a natural killer-like phenotype and express cytotoxic granules upon activation.⁷²⁵ Keratinocytes at the site of a fixed drug eruption express one of the cell adhesion molecules (ICAM-1) that is involved in the adherence reaction between lymphocytes and epidermal keratinocytes.⁷²⁶ It has been suggested that localized expression of this adhesion antigen may be one factor that explains the site specificity of fixed drug eruptions.⁷²⁶ The occurrence of some fixed drug eruptions at sites of trauma or previous inflammation may be a manifestation of an isotopic response.⁶³³ It is also possible that preformed cytokines may exist at such sites. These findings have been incorporated into the following hypothesis: the causative drug activates mast cells or keratinocytes to release cytokines or induces keratinocytes to express adhesion molecules on their surfaces, leading to the activation of epidermal CD8⁺ T cells⁷²⁷ and resulting in death of keratinocytes by a FasL-mediated pathway.¹⁵⁵ This theory has been put forward in an attempt to explain the early onset of symptoms, which occur much earlier than traditional cell-mediated responses could produce.

Although CD8⁺ cells are more numerous than CD4⁺ cells in the epidermis and dermis, cells that are CD25⁺ CD4⁺ appear to migrate into the epidermis of active lesions and exert a regulatory function by releasing IL-10, resulting in the resolution of the lesion(s).¹⁵⁵ These same cells have also been shown to be involved in the induction of desensitization to a fixed drug eruption.¹⁵⁵

There appears to be a genetic susceptibility to fixed drug eruptions, with an increased incidence of HLA-B22⁷²⁸ and HLA-A30 B13 Cw6.⁷²⁹

Histopathology^{617,731}

Established lesions show a lichenoid reaction pattern with prominent vacuolar change and Civatte body formation (Fig. 3.17). The degenerate keratinocytes usually show less shrinkage than in lichen planus. The inflammatory infiltrate tends to obscure the dermoepidermal interface, as in erythema multiforme and some cases of pityriasis lichenoides et varioliformis acuta (PLEVA). The infiltrate often extends into the mid and upper epidermis, producing death of keratinocytes above the basal layer (Fig. 3.18). Fixed drug eruptions can usually be distinguished

Figure 3.17 Fixed drug eruption. Dead keratinocytes are present in the basal layer and at higher levels of the epidermis. Lymphocytes extend into the epidermis. (H&E)

Figure 3.18 Fixed drug eruption. (A) The infiltrate of lymphocytes extends some distance into the epidermis, resulting in cell death in the basal layer and above. (H&E) (B) In this early stage lesion, there are spongiosis, dermal edema, and neutrophilic aggregates within the dermis with exocytosis.

from erythema multiforme by the deeper extension of the infiltrate, the presence of a few neutrophils, and the more prominent melanin incontinence in fixed eruptions.

Based on one study,⁷³⁰ it appears that very early lesions may show epidermal spongiosis, dermal edema, neutrophil microabscesses, and numerous eosinophils in the dermis. These features have usually disappeared after several days, although some eosinophils persist (Fig. 3.18B).

The clinical variants of fixed drug eruption have not been documented very well, except for the bullous form which results when subepidermal clefting occurs. This may be misdiagnosed as erythema multiforme. Spongiotic vesiculation is present in the eczematous variant, and a picture resembling an urticarial reaction is seen in others. Vasculitis is another pattern seen, rarely, in fixed drug eruptions.⁶⁷⁵ In the nonpigmenting variant, there is a mild perivascular and interstitial mixed inflammatory infiltrate in the dermis.⁶²²

Electron microscopy

There is prominent clumping of tonofilaments in the cytoplasm of basal keratinocytes, which provides an explanation for the bright eosinophilic cytoplasm and the comparatively small amount of shrinkage that these cells undergo during cell death.⁶²⁰ There is also condensation of nuclear chromatin. Intracytoplasmic desmosomes are sometimes seen. Filamentous bodies, composed of filaments that are less electron-dense than in the intact cells, are quite numerous.⁷³¹ These contain some melanosomes and sometimes nuclear remnants.⁶²⁰ They are sometimes phagocytosed by adjacent keratinocytes or macrophages.⁶²⁰ The accumulation of tonofilaments may represent a response by keratinocytes to sublethal injury or some other stimulus. It has the effect of masking the exact mode of death – apoptosis or necrosis. The term ‘filamentous degeneration’ has some merit in these circumstances.

Differential diagnosis

The chief consideration in the microscopic differential diagnosis is *erythema multiforme*, a condition that shares the features of vacuolar alteration of the basilar layer, apoptotic keratinocytes, often at all levels of the epidermis, and a perivascular dermal infiltrate. Clinically, the history of an isolated lesion recurring at the same site certainly favors fixed drug eruption, but multiple or widespread lesions can occur, sometimes confounding the clinical diagnosis. In contrast to erythema multiforme, which tends to show a relatively mild superficial dermal perivascular lymphocytic infiltrate, fixed drug eruption tends to show a superficial and deep dermal infiltrate that contains neutrophils as well as lymphocytes. When present, intraepidermal vesiculation also favors fixed drug eruption because bullae in erythema multiforme are subepidermal. Some examples of *pityriasis lichenoides* acuta can closely resemble erythema multiforme and, by extension, can also mimic fixed drug eruption. However, the wedge-shaped dermal infiltrate in *pityriasis lichenoides* is composed mainly of lymphocytes, and vascular changes qualify as lymphocytic vasculitis. Neutrophils, if present, are generally confined to the surface of necrotic lesions. Early lesions of fixed drug eruption that show intraepidermal vesiculation on the basis of intracellular edema can bear a resemblance to *herpes simplex* or *varicella-zoster infection* of the skin, but the formation of multinucleated giant cells, characteristic nuclear changes, and intranuclear inclusions of the latter disorders are not observed, and immunohistochemical stains for herpes viruses are negative. Isolated examples of ‘neutrophilic’ fixed drug eruption could resemble other intraepidermal pustular conditions, including *acute generalized exanthematous pustulosis* and *herpetiform or IgA pemphigus*. In addition to the characteristic clinical presentation, fixed drug eruption would also be expected to show significant interface changes, and direct IF studies would fail to show intercellular IgG, IgA, or C3 deposition as would be characteristic of forms of pemphigus.

ERYTHEMA MULTIFORME

Erythema multiforme is a self-limited, sometimes episodic disease of the skin, which may also involve the mucous membranes. It is characterized by a pleomorphic eruption consisting of erythematous macules, papules, urticarial plaques, vesicles, and bullae.^{732,733} Individual lesions may evolve through a papular, vesicular, and target (iris) stage in which bullae surmount an erythematous maculopapule.⁷³⁴ Lesions tend to be distributed symmetrically with a predilection for the extremities, particularly the hands.

Clinical variants

In the past, erythema multiforme was classified into *erythema multiforme minor* and *erythema multiforme major*, the latter being characterized by a severe and sometimes fatal illness in which fever, systemic symptoms, and severe oral lesions were usually present.^{734–737} The term *Stevens–Johnson syndrome* was also applied to these severe cases with oral involvement. Recently, an attempt has been made to distinguish Stevens–Johnson syndrome from erythema multiforme major with mucosal lesions on the basis of their different *cutaneous* lesions and their etiology;⁷³⁸ their *mucosal* lesions are similar. Stevens–Johnson syndrome is said to be characterized by flat atypical target lesions or purpuric macules that are widespread or limited to the trunk. Erythema multiforme major with mucosal lesions has typical or raised atypical target lesions, located on the extremities and/or the face.⁷³⁸ Using these definitions, Stevens–Johnson syndrome is usually related to drugs and erythema multiforme to herpes or other infections.^{738,739}

In a prospective European study involving 552 patients, erythema multiforme major was found to differ from Stevens–Johnson syndrome and toxic epidermal necrolysis not only in severity but also in several demographic features.⁷⁴⁰ Erythema multiforme major occurred in younger males and had frequent recurrences; less fever; milder mucosal lesions; and a lack of association with collagen vascular diseases, HIV infection, or cancer.⁷⁴⁰ Recent or recurrent herpes simplex infection was the principal risk factor.⁷⁴⁰

The criteria used to distinguish the component diseases that form this spectrum have been criticized on the basis that they ignore the fundamental clinical differences between these two related conditions.⁷⁴¹ Namely, Stevens–Johnson syndrome is associated with systemic symptoms and involvement of internal organs, whereas erythema multiforme is not.⁷⁴¹ **Toxic epidermal necrolysis** (discussed later) has variously been regarded as a separate entity or as representing the severe end of the spectrum of erythema multiforme major or Stevens–Johnson syndrome.^{742,743} Some clinicians have arbitrarily diagnosed toxic epidermal necrolysis when blisters and peeling involved more than 30% of the total body surface area and Stevens–Johnson syndrome when mucosal lesions were present and blistering involved less than 30% of the body surface.⁷⁴⁴ An international group has attempted to standardize the terminology by defining five clinical categories – bullous erythema multiforme, Stevens–Johnson syndrome, overlap Stevens–Johnson syndrome/toxic epidermal necrolysis, toxic epidermal necrolysis with ‘spots’ (widespread purpuric macules or target lesions), and toxic epidermal necrolysis without ‘spots’.^{744,745} The strategy behind this approach is summarized by two of the experts in this area: “Our current concept is to separate an EM spectrum (EM minor combined with EM major) from an SJS/TEN spectrum.”⁷⁴⁶ Many clinicians use only three categories – erythema multiforme, Stevens–Johnson syndrome, and toxic epidermal necrolysis – making comparative studies of this clinical spectrum difficult.

Two further clinical subgroups have been delineated: *recurrent erythema multiforme* and a rare *persistent* form. The persistent form has been associated with an underlying malignancy and with Epstein–Barr virus infection.^{747,748} Some cases are idiopathic.⁷⁴⁹ The recurrent form

is frequently associated with recurring infections,⁷⁵⁰ often with the herpes simplex virus.^{751,752} Rarely it is associated with hepatitis C infection.⁷⁵³ Sometimes the recurrent lesions mimic polymorphic light eruption by having a photodistribution.⁷⁵⁴ Patients with certain HLA types – B35, B62 (B15), and DR53 – are more susceptible to this recurrent form.⁷⁵⁵

Unusual clinical presentations include the limitation of lesions to areas of lymphatic obstruction,⁷⁵⁶ to nevi,^{757,758} or to Blaschko's lines;⁷⁵⁹ a photosensitive eruption;⁷⁶⁰ and the development of eruptive nevocellular nevi following severe erythema multiforme.⁷⁶¹ Long-term follow-up suggests that nevi that develop after bullous disorders are more likely to remain benign compared to those in patients with ongoing immunosuppression.⁷⁶² Leukoderma is a rare complication.⁷⁶³

Neonatal erythema multiforme may be difficult to diagnose and manage.^{764–766} Fortunately, it is quite rare.

Etiology and pathogenesis

More than 100 different causal factors have been implicated, including viral and bacterial infections, drugs, and several associated neoplastic conditions.⁷⁶⁷ Infection with herpes simplex type 1 is a common precipitating factor for minor forms,^{768–770} whereas *Mycoplasma pneumoniae* infection^{771,772} and drugs are often incriminated in the more severe cases.^{735,773} A study of erythema multiforme in children found that the minor forms were due to herpes simplex and the cases with Stevens–Johnson syndrome to *M. pneumoniae* infection.^{774–777} Drugs were rarely implicated in this age group.⁷⁷⁴ *Mycoplasma pneumoniae* can produce a mucositis, as seen in Stevens–Johnson syndrome, but without skin lesions.^{778,779} Infection with Epstein–Barr virus has been associated with both minor and persistent erythema multiforme.^{747,780,781} Other infections shown to be associated with erythema multiforme include cytomegalovirus,^{782,783} Lyme disease (in its early stages),^{784,785} syphilis,⁷⁸⁶ orf,⁷⁸⁷ molluscum contagiosum,⁷⁸⁸ various dermatophytes,^{789–791} sporotrichosis,⁷⁹² brucella,⁷⁹³ *Chlamydia pneumoniae*,⁷⁹⁴ Kikuchi disease,⁷⁹⁵ *Gardnerella vaginalis*,⁷⁹⁶ HTLV-1, and hepatitis B.^{797,798} It has also followed hepatitis B immunization⁷⁹⁹ and immunization with smallpox, anthrax, and tetanus vaccines,⁸⁰⁰ and diphtheria–pertussis–tetanus vaccine.⁸⁰¹

Numerous drugs have been involved, most commonly the sulfonamides and nonsteroidal anti-inflammatory drugs.^{802–804} They often produce a severe reaction. Corticosteroids may occasionally be culprit drugs.⁸⁰⁵ Specific drugs incriminated include ciprofloxacin,^{806,807} ofloxacin,⁸⁰⁸ nystatin,⁸⁰⁹ the aminopenicillins,⁸¹⁰ doxycycline,^{811,812} cimetidine, suramin,⁸¹³ theophylline,⁸¹⁴ allopurinol, etretinate,⁸¹⁵ terbinafine,^{816–820} griseofulvin,⁸²¹ clonazepam,⁸²² acarbose,⁸²³ ticlopidine,⁸²⁴ sertraline,^{804,824} rofecoxib,⁸²⁵ valdecoxib,⁸²⁶ amifostine,⁸²⁷ cyclophosphamide,⁸²⁸ lamotrigine,^{804,829–831} bezafibrate,⁸³² cocaine,⁸³³ phenytoin,^{834,835} progesterone in a low-dose oral contraceptive pill,⁸³⁶ sennoside,⁸³⁷ amifostine,⁸³⁸ thalidomide,⁸³⁹ ramipril,⁸⁴⁰ the contrast medium iopentol,⁸⁴¹ fenoterol,⁸⁴² the multikinase inhibitor sorafenib,⁸⁴³ pantoprazole,⁸⁰⁴ tramadol,⁸⁰⁴ irbesartan,⁸⁴⁴ bupropion,⁸⁴⁵ topical nitrogen mustard,⁸⁴⁶ mefloquine,⁸⁴⁷ trichloroethylene,⁸⁴⁸ the Chinese herbal drug 'Dong Ling Hou Tong Pian',⁸⁴⁹ and nevirapine.^{804,850,851} It has been reported that allopurinol is now the most common cause of Stevens–Johnson syndrome and toxic epidermal necrolysis in Europe and Israel.⁸⁵² The various drugs that have precipitated erythema multiforme/toxic epidermal necrolysis are listed in Table 3.5.

Erythema multiforme has been reported in association with an allergic contact dermatitis; plants, poison ivy,⁸⁵³ woods,⁸⁵⁴ paraphenylenediamine in a henna tattoo,⁸⁵⁵ epoxy sealants, and diphenylprone (used in the treatment of warts) have been incriminated.^{856–858} It has also followed polymorphic light eruption.⁸⁵⁹ An erythema multiforme-like reaction has been reported following the intravenous injection of vinblastine in the vicinity⁸⁶⁰ and at sites of radiation therapy in patients taking antiepileptic drugs.⁸⁶¹

Erythema multiforme appears to result from a cell-mediated immune reaction to one of the many agents listed previously. In the case of herpes simplex, lymphocytes home to viral antigen-positive cells containing the herpes DNA polymerase gene (*Pol*).^{862,863} The term HAEM (herpes-associated erythema multiforme) is used for these cases. The virus often remains in affected cutaneous sites for up to 3 months or more following resolution of the erythema multiforme, suggesting that the skin may function as a site of viral persistence.^{864,865} Herpes simplex virus can be detected in up to three-fourths of patients with erythema multiforme, on paraffin-embedded biopsy material.^{866–868} Two classes of lymphocytes appear to be involved in this cell-mediated reaction: T lymphocytes carrying the Vβ2 phenotype⁸⁶⁹ and CD8⁺ cells with natural killer cell activity.⁸⁷⁰ CD4⁺ T lymphocytes appear to be more important in erythema multiforme and CD8⁺ cells in Stevens–Johnson syndrome/toxic epidermal necrolysis.⁸⁷¹ The proportions of granulysin⁺ and perforin⁺ CD8⁺ cells are higher, while the numbers of Foxp3⁺ regulatory cells and CD4⁺ cells are lower, in Stevens–Johnson syndrome/toxic epidermal necrolysis compared to erythema multiforme major.⁸⁷² The effector cytokine is IFN-γ in cases of HAEM, whereas in drug-induced erythema multiforme major/Stevens–Johnson syndrome/toxic epidermal necrolysis, tumor necrosis factor (TNF-α), perforin, and granzyme B produce the epidermal destruction.^{803,873–875} This is a simplistic explanation of the pathogenesis because numerous other chemokines are involved or differentially expressed.⁸⁷⁶ For example, the Fas and FasL systems are only weakly expressed in erythema multiforme compared with toxic epidermal necrolysis⁸⁷¹ so that presumably this apoptotic pathway does not play a pivotal role in erythema multiforme. Likewise, there are fewer CD40L⁺ cells in erythema multiforme.⁸⁷¹ The finding of autoantibodies against desmoplakin I and II is probably an epiphenomenon.^{877–879}

The value of systemic corticosteroids in the treatment of erythema multiforme is hotly debated. Some relief of systemic symptoms is achieved, but there is no evidence that their use improves the overall mortality or long-term morbidity.⁸³³ Control with thalidomide has been achieved. The role of antivirals is controversial, but prophylactic antiviral therapy with acyclovir (aciclovir) or valacyclovir (valaciclovir) inhibits HSV reactivation in recurrent cases and prevents HAEM development.⁸⁷⁷ Recurrent erythema multiforme/Stevens–Johnson syndrome has responded to mycophenolate mofetil.⁸⁸⁰ Dapsone, IFN-α,⁸⁸¹ and intravenous immunoglobulins combined with corticosteroids have all been successful in the treatment of some cases.

Histopathology^{735,882,883}

In established lesions, there is a lichenoid (interface) reaction pattern with a mild to moderate infiltrate of lymphocytes, some of which move into the basal layer, thereby obscuring the dermoepidermal interface (Fig. 3.19). Some of the intraepidermal lymphocytes are of the large granular subtype.⁸⁸⁴ This is associated with prominent epidermal cell death, which is not confined to the basal layer. Apoptosis is the mechanism of cell death.⁸⁸⁵ There is also basal vacuolar change and some epidermal spongiosis.⁸⁸² One study found that an acrosyringeal concentration of apoptotic keratinocytes in erythema multiforme is a clue to a drug etiology. These changes are likely to be accompanied by an inflammatory infiltrate containing eosinophils.⁸⁸⁶

Vesicular lesions are characterized by clefting at the dermoepidermal junction and prominent epidermal cell death in the overlying roof (Fig. 3.20). This may involve single cells or groups of cells, or it may take the form of confluent necrosis.

The dermal infiltrate in erythema multiforme is composed of lymphocytes and a few macrophages involving the superficial and mid-dermal vessels and a more dispersed infiltrate along and within the basal layer. In severe cases of erythema multiforme showing overlap features with toxic epidermal necrolysis (discussed later), the infiltrate

Figure 3.19 Erythema multiforme. (A) An early case from the dorsum of the hand. (B) A more established case in which cell death involves keratinocytes within and above the basal layer. The infiltrate of lymphocytes tends to obscure the dermoepidermal interface. (H&E)

Figure 3.20 Erythema multiforme with early subepidermal vesiculation. Preservation of the basket-weave pattern of the stratum corneum is a characteristic feature. (H&E)

may be quite sparse with confluent necrosis of the detached overlying epidermis. Eosinophils are not usually prominent in erythema multiforme, although they have been specifically mentioned as an important feature in some reports.^{882,887-889} We have seen a case with numerous dermal eosinophils with eosinophilic microabscesses in the epidermis.⁸⁹⁰ Likewise, a vasculitis has been noted by some⁸⁹¹ but specifically excluded by most.^{882,883,892} Nuclear dusting, not related to blood vessels, is sometimes present.⁸⁹³

Erythema multiforme has been divided in the past into epidermal, dermal, and mixed types based on the corresponding predominant histological features.⁸⁹³ In the epidermal type, there was prominent epidermal damage. In the dermal type, there was pronounced dermal papillary edema leading to subepidermal vesiculation; some basal epidermal damage was seen in some areas of the biopsy. It seems likely that diseases other than erythema multiforme – severe urticarias and urticarial vasculitis – have been included in this category of dermal erythema multiforme. There is little merit in the continued separation of these three histological subtypes.⁸⁹⁴ The rare cases with subcorneal pustules are probably not variants of erythema multiforme as reported.⁸⁹⁵

Erythema multiforme-like changes can be seen in biopsies taken from the hypersensitivity reactions to phenytoin, carbamazepine, and related drugs. Interestingly, the clinical picture does not resemble erythema multiforme.

Direct immunofluorescence shows intraepidermal cytoid bodies, representing degenerate keratinocytes, which stain in a homogeneous pattern usually with IgM and sometimes C3.⁸⁹⁶ Frequently, there is granular staining for C3 along the dermoepidermal junction and, in early lesions, also in papillary dermal vessels.^{897,898} The presence of properdin suggests activation of the alternate complement pathway.⁸⁹⁸ Matrix metalloproteinases 2, 9, and 11 are expressed in erythema multiforme.⁸⁹⁹

Differential diagnosis

The constellation of features in erythema multiforme is sufficiently characteristic to permit a diagnosis in most instances. Early papular or urticarial lesions (or biopsies obtained from the edematous outer ring of a targetoid lesion) may be the most problematic due to their nonspecific features. Most immunobullous diseases look quite different from erythema multiforme and can easily be excluded on a routine biopsy, with or without supplementation by direct immunofluorescence. One possible exception is *paraneoplastic pemphigus* because erythema multiforme-like changes can be seen in some biopsies of this condition (see p. 167). Usually, foci of suprabasilar acantholysis will be seen in some areas of the biopsy. Distinctive immunofluorescence changes are also present in paraneoplastic pemphigus (intercellular and, sometimes, basement membrane zone fluorescence). Other differential diagnostic considerations include fixed drug eruption and pityriasis lichenoides acuta. Biopsies of *fixed drug eruption* show epidermal changes that often closely mimic erythema multiforme, but there is a superficial and deep perivascular dermal infiltrate in fixed drug eruption, and neutrophils may be more evident. The spongiotic variant of fixed drug eruption, with prominent eosinophils and neutrophils, would be readily distinguishable from erythema multiforme (discussed previously). *Pityriasis lichenoides acuta* at times can closely mimic erythema multiforme microscopically, but usually there is a greater degree of parakeratosis and exocytosis of inflammatory cells in the former, and the dermal infiltrate may be more wedge-shaped and show evidence for lymphocytic vasculitis. Two other conditions that can resemble erythema multiforme microscopically but have substantially different clinical presentations are *graft-versus-host disease* and occasional examples of *exfoliative dermatitis* due to drugs, underlying neoplasm, or distant focus of infection.

Toxic epidermal necrolysis

Toxic epidermal necrolysis (TEN), regarded as the most severe form of an erythema multiforme spectrum, presents with generalized tender erythema that rapidly progresses into a blistering phase with extensive shedding of skin.^{898,900–907} Erosive mucosal lesions are usually present. Multiple intestinal ulcers have also been reported.⁸⁵⁵ The mortality approaches 35%.^{907,908} The risk of death can be predicted from the quantitative 'severity of illness' score (SCORTEN).⁹⁰⁹ However, respiratory involvement in TEN portends a poor prognosis that may not be reflected in SCORTEN.⁹¹⁰ The extent of the necrolysis (skin shedding) is one of the principal prognostic factors, and a classification system based on the extent of epidermal detachment has therefore been proposed:^{746,911}

1. Stevens–Johnson syndrome – mucosal erosions and epidermal detachment below 10% of total body area
2. Stevens–Johnson syndrome/toxic epidermal necrolysis overlap (SJS/TEN) – epidermal detachment between 10 and 30%
3. Toxic epidermal necrolysis – epidermal detachment more than 30%.

Drugs are incriminated in the etiology in the majority of cases,⁹¹² particularly sulfonamides,⁹¹³ anticonvulsants,^{914–918} selective serotonin reuptake inhibitors (SSRIs),⁹¹⁹ and nonsteroidal anti-inflammatory drugs such as phenylbutazone, isoxicam, and piroxicam.^{920,921} The incidence of TEN in adults secondary to trimethoprim–sulfamethoxazole has been calculated to be 2.6 per 100,000 exposures, whereas in patients who are HIV-positive, the rate is 8.4 cases per 100,000 exposures.⁹²² Specific drugs implicated include allopurinol,^{852,923–925} ranitidine,^{926,927} clindamycin,⁹²⁸ telithromycin,⁹²⁹ clarithromycin,^{930,931} moxifloxacin,⁹³² isoniazid,⁹¹⁸ thiacetazone,⁹¹⁸ chloroquine,⁹³³ hydroxychloroquine,^{934,935} amphetamines (including 'speed'),^{936,937} tetrazepam,^{938,939} famotidine,⁹⁴⁰ indapamide,⁹⁴¹ clobazam,⁹⁴² oxaprozin,⁹⁴³ pseudoephedrine,⁹⁴⁴ diacerein,⁹⁴⁵ methotrexate,^{946,947} leflunomide,⁹⁴⁸ lansoprazole,^{949,950} cytosine arabinoside,⁹⁵¹ lamotrigine,^{952–954} voriconazole,⁹²² rituximab,⁹²² imatinib,⁹²² carbamazepine,^{954–956} latanoprost eye drops (with timolol and dorzolamide in one case),⁹⁵⁷ trimethoprim–sulfamethoxazole,^{958,959} ceftazidime,⁹⁶⁰ vancomycin,^{960,961} ciprofloxacin,⁹⁶² colchicine,⁹⁶³ acetaminophen (paracetamol),⁹⁶⁴ nevirapine,^{965,966} the SSRIs (fluvoxamine, paroxetine, fluoxetine, sertraline, citalopram, and escitalopram),⁹¹⁹ mefloquine,⁸⁴⁷ mifepristone/gemeprost,⁹⁶⁷ alfuzosin,⁹⁶⁸ oxazepam,⁹⁶⁹ ritodrine/indomethacin/betamethasone therapy for preterm labor,⁹⁷⁰ ampicillin/sulbactam,⁹⁷¹ phenytoin,⁹¹⁷ zonisamide associated with reactivation of HHV-6,⁹⁷² and ethambutol.⁹¹⁷

Another association of toxic epidermal necrolysis includes angioimmunoblastic T-cell lymphoma.⁹⁷³

The pathogenesis is uncertain, but it appears that most patients with toxic epidermal necrolysis have an abnormal metabolism of the offending drug, which leads to an increased production of reactive metabolites.^{746,915} Some genetic susceptibility is suggested by the increased incidence of HLA-B12 in affected individuals.^{974,975} A strong association has been found between allopurinol-induced SJS/TEN and HLA-B*5801.⁹⁷⁶ It has developed in a mother and her 22-week-old fetus⁹⁷⁷ and also in a premature infant.⁹⁷⁸

Epidermal necrosis is probably mediated by cytokines from drug-specific cytotoxic T lymphocytes,⁹⁷⁹ such as TNF- α ,^{803,873,980,981} but it is unlikely this is the only mediator of epidermal damage (see later).⁹⁸² Apoptosis of keratinocytes also occurs.⁹⁸³ It is thought that this may result from the interaction between the death receptor Fas (CD95) and its ligand present on epidermal cells.⁹⁸⁴ The action of cytokines would explain the apparent discrepancy between the extent of the damage and the paucity of the dermal infiltrate.

The majority of nonkeratinocytic cells in the epidermis are CD8⁺ lymphocytes and macrophages, whereas the lymphocytes in the papillary dermis are CD4⁺.^{985–987} Although the cell-mediated immune

response is characterized, in part, by a Th1 profile, there is increasing evidence in favor of the development of a Th2-mediated response in SJS/TEN, whereas erythema multiforme is characterized by a dominant Th1 profile.^{988,989} Drug-specific CD8⁺ T lymphocytes appear to be the main triggering agents of the massive epidermal damage in SJS/TEN by secretion of perforin, granzyme B, and cytokines such as TNF- α .^{871,975,990} Furthermore, the interaction between Fas and Fas ligand triggering the caspase cascade is another mechanism of apoptosis, but it may not be the critical mediator of cell death as once thought.⁹⁸² The CD40/CD40L pathway is yet another mechanism of cell damage.⁹⁹¹ Serum IL-13 levels are also increased in SJS/TEN but not in erythema multiforme.⁹⁸⁸ There are elevated levels of IL-10, IL-6, IL-8, IL-2 receptor, and TNF- α in blister fluid.^{992–994} Blister fluid from patients with TEN has been found to contain functionally active myeloperoxidase, apparently produced by macrophages; myeloperoxidase can lead to production of the oxidative compound hypochlorous acid, capable of producing keratinocyte alteration.⁹⁹⁵ Another study found that CD1a⁺ and CD14⁺ cells in blister fluids secrete TRAIL (tumor necrosis factor-related apoptosis-inducing ligand) and TWEAK (TNF-like weak inducer of apoptosis) – ligands that can induce keratinocyte death.⁹⁹⁶ The sera from patients with TEN contain autoantibodies to periplakin that may play a role in the pathogenesis as a humoral autoimmune mechanism.⁹⁹⁷ Antidesmoplakin autoantibodies also circulate.⁹⁹⁸

Patients on corticosteroid therapy may still develop TEN; corticosteroids may delay the onset of the disease but not halt its progression.^{999,1000} Patients infected with the human immunodeficiency virus may develop toxic epidermal necrolysis similar to immunocompetent patients.^{1001–1003}

Management of severe SJS and TEN includes prompt withdrawal of the offending drug, referral to a burn or specialized dermatology unit, good nursing care, management of infection, and wound debridement. Treatments that have been recommended but not subjected to placebo-controlled trials include intravenous immunoglobulin, infliximab,¹⁰⁰⁴ N-acetylcysteine, pentoxifylline,^{1005,1006} and cyclosporin.⁹³⁷

Histopathology^{902,1007}

There is a subepidermal bulla with overlying confluent necrosis of the epidermis and a sparse perivascular infiltrate of lymphocytes (Fig. 3.21). In early lesions, there is some individual cell necrosis that may take the form of lymphocyte-associated apoptosis (satellite cell necrosis) with an adjacent lymphocyte or macrophage. This has been likened to the

Figure 3.21 Toxic epidermal necrolysis. There is a subepidermal cell-poor blister with epidermal necrosis in the roof. (H&E) A diffuse deposition of immunoreactants has been found in the mid-epidermis on immunofluorescence.¹⁰¹⁷

changes of graft-versus-host disease (GVHD; see later).^{901,1008} In established lesions of TEN, there is full-thickness epidermal necrosis, which is not seen in GVHD.¹⁰⁰⁸ A more prominent dermal infiltrate is seen in those cases that overlap with erythema multiforme. If the degree of dermal mononuclear inflammation is quantified, some prognostic information, equivalent to that provided by SCORTEN, can be obtained.¹⁰⁰⁹ In one study of 37 patients, 73% of patients ($n = 11$) with sparse inflammation survived, but only 47% ($n = 7$) with moderate and 29% ($n = 2$) with extensive inflammation survived.¹⁰⁰⁹ Neutrophilic inflammation and sometimes pustule formation have been documented in rare cases.¹⁰¹⁰⁻¹⁰¹² Sweat ducts show a variety of changes ranging from basal cell apoptosis to necrosis of the duct.¹⁰¹³ In the healing phase, milia and disturbances of pigmentation are common. Scarring and keloids may also develop. Verrucous hyperplasia of the epidermis is a rare response.¹⁰¹⁴ Vulval and vaginal adenosis are other late responses.^{1015,1016}

Differential diagnosis

The full-thickness epidermal necrosis of TEN must be distinguished from epidermal necrosis due to ischemia. In such cases, the dermis often has a homogeneous, dusky degenerative appearance. Vascular compromise can be further suggested by necrosis of deeper dermal/subcutaneous eccrine sweat coils and sometimes verified by the detection of thrombi/emboli, calciphylaxis changes, or evidence for vasculitis. Exposure to superficial toxic agents can produce epidermal necrosis with minimal inflammation. Several reports have described severe forms of acute generalized exanthematous pustulosis that mimicked TEN.^{1018,1019} This uncommon scenario arises because rare cases of TEN can have a pustular component, whereas rare examples of acute generalized exanthematous pustulosis can apparently demonstrate bulla formation with extensive skin detachment. Strict attention to the histopathologic findings can usually aid in this differentiation because, in contrast to TEN, acute generalized exanthematous pustulosis should show subcorneal and intraepidermal pustules with mild spongiform pustulation, papillary dermal edema, a neutrophilic perivascular infiltrate that sometimes has the characteristics of vasculitis, and minimal apoptosis.¹⁰²⁰ An important clinical differential consideration for TEN is *staphylococcal scalded skin syndrome*, a primarily childhood disease due to the effects of exfoliative exotoxins types A and B. However, the latter disease typically has a much better prognosis and microscopically shows only superficial rather than full-thickness epidermal necrosis. This can be determined not only on routine biopsy specimens but also in a rapid procedure performed on frozen sections of separated skin.

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease is a systemic syndrome with important cutaneous manifestations. It is usually seen in patients receiving allogeneic immunocompetent lymphocytes in the course of bone marrow transplants used in the treatment of aplastic anemia,¹⁰²¹ leukemia, or in immunodeficiency states.^{784,1022-1026} Acute GVHD develops in approximately one-third of HLA-matched recipients of allogeneic bone marrow.^{1027,1028} It also follows stem cell transplantation.¹⁰²⁹ Risk factors for the development of acute cutaneous GVHD after allogeneic stem cell transplantation include a diagnosis of chronic myeloid leukemia, HLA disparity, and conditioning regimens such as total body irradiation.¹⁰²⁹ It may also occur following maternofetal blood transfusions *in utero*,¹⁰³⁰ intrauterine exchange transfusions, and the administration of non-irradiated blood products to patients with disseminated malignancy and a depressed immune system.¹⁰³¹⁻¹⁰³⁷ It is seen only rarely after solid organ transplantation.^{1038,1039} It is also less common with cord blood than with bone marrow transplants in children receiving either

product from HLA-identical siblings.¹⁰⁴⁰ Rarely, immunocompetent patients are at risk, particularly those subject to cardiac surgery.¹⁰⁴¹⁻¹⁰⁴³ The acute stage can be precipitated in some individuals by autologous and syngeneic bone marrow transplantation,¹⁰⁴⁴⁻¹⁰⁴⁶ chronic lesions (see later), particularly lichenoid ones, are rare.¹⁰⁴⁷ Acute GVHD superimposed on pre-existing lichenoid chronic GVHD has been reported; it followed reinduction chemotherapy.¹⁰⁴⁸ GVHD has been reported in patients with a thymoma or lymphoma.¹⁰⁴⁹⁻¹⁰⁵² Sclerodermoid GVHD-like lesions have also developed long after the clinical resolution of drug-induced hypersensitivity syndrome.¹⁰⁵³

There is an early acute phase with vomiting, diarrhea, hepatic manifestations, and an erythematous macular rash.^{1024,1054,1055} Rarely, it is confined to the flexures.¹⁰⁵⁶ Uncommonly, there are follicular papules¹⁰⁵⁷ or blisters;¹⁰⁵⁸ rarely, toxic epidermal necrolysis ensues.^{1024,1059} Just two erythematous nodules were the presenting features in one case.¹⁰⁶⁰ A pustular acral erythema with associated eccrine squamous syringometaplasia has also been reported.¹⁰⁶¹ Ichthyosiform features may occur in both acute and chronic forms.^{1062,1063} Localization to an area of skin affected by piebaldism, and in another case herpes zoster, has been reported.^{1064,1065} Lichenoid nail changes also occur.¹⁰⁶⁶ They usually persist in chronic disease.¹⁰⁶⁷ The chronic stage develops some months or more after the transplant. A preceding acute stage is present in 80% of these patients.^{1024,1068} Chronic GVHD has an early lichenoid phase that resembles lichen planus and includes oral lesions.^{1069,1070} Linear lichenoid lesions have been reported both in a dermatomal distribution and following Blaschko's lines.¹⁰⁷¹⁻¹⁰⁷⁵ Rarely, dermatomal lesions occur at sites of varicella-zoster infection.^{1075,1076} A poikilodermatous phase may precede the eventual sclerodermoid phase. The lesions of the latter may be localized¹⁰⁷⁷ or generalized.^{1024,1078} Sclerodermatous GVHD (see p. 357) has a prevalence of approximately 3% in patients receiving allogeneic bone marrow transplants.¹⁰⁷⁹ Other late manifestations include alopecia, a lupus erythematosus-like eruption, cicatrizing conjunctivitis,¹⁰⁸⁰ pyogenic granuloma and angiomatous lesions,¹⁰⁸¹ wasting, diffuse melanoderma,¹⁰⁸² leukoderma and leukotrichia,¹⁰⁸³ esophagitis, liver disease, and the sicca syndrome. Acute GVHD may be a late manifestation (>100 days after transplantation), following the suspension or tapering of immunosuppressive drugs. It can be seen after traditional transplants and the newer nonmyeloablative technique.¹⁰⁸⁴ Late-onset acute GVHD is a predictor of chronic GVHD.¹⁰⁸⁴

The pathogenesis appears to be complex,¹⁰⁸⁵ but the essential factor is the interaction of donor cytotoxic T lymphocytes with recipient minor histocompatibility antigens.¹⁰⁸⁶⁻¹⁰⁸⁸ Several effector cell populations appear to be involved.^{1089,1090} Recent work suggests that this is an oversimplistic explanation of the pathogenesis.¹⁰⁹¹ Not only is direct cellular cytotoxicity involved but also soluble mediators such as IFN- γ , CXCR3, TNF- α , FasL, and TRAIL play a significant role in the pathogenesis of acute GVHD.^{1091,1092} Young rete ridge keratinocytes¹⁰⁹³ and Langerhans cells^{1088,1094} are preferred targets. The acute stage is associated with HLA-DR expression of keratinocytes.¹⁰⁹⁵⁻¹⁰⁹⁷ Factor XIIIa-positive dermal dendrocytes appear to play some role,^{1098,1099} possibly in the regulation of the connective tissue remodeling that follows epidermal destruction. Recent work suggests that HHV-6 reactivation may play a role in the pathogenesis of rash/GVHD after allogeneic stem cell transplantation.¹¹⁰⁰ There is experimental evidence that platelet-activating factor receptor may play a role in the pathogenesis of the disease through its role in mediating leukocyte influx and cytokine production.¹¹⁰¹ Scleroderma-like skin lesions in chronic GVHD could be linked to antibodies directed against human cytomegalovirus late protein UL94; this occurs due to molecular mimicry between the UL94 viral protein and the NAG-2 molecule (tetraspanin-4, a cell surface protein). Such antibodies induce endothelial cell apoptosis and fibroblast proliferation.¹¹⁰² The treatment of acute GVHD is beyond the scope of this book, involving as it does a disease in which the cutaneous manifestations may be a small component of a systemic disease. Chronic cutaneous GVHD has been treated with

corticosteroids and immunosuppressants such as cyclosporine. They have had a limited effect on the disease, not to mention the long-term effects of corticosteroids. Chronic disease may also be treated by extracorporeal photopheresis (ECP).¹¹⁰³ It also induces, as a side effect, immediate and progressive apoptosis.¹¹⁰⁴ A consensus statement on its use was published in 2008.¹¹⁰³ UVA1 phototherapy,¹¹⁰⁵ tacrolimus ointment,¹¹⁰⁶ and pimecrolimus¹¹⁰⁷ have also been used in chronic cutaneous GVHD.

Histopathology^{1024,1108}

In early *acute lesions*, there is a sparse superficial perivascular lymphocytic infiltrate with exocytosis of some inflammatory cells into the epidermis. The number of these cells correlates positively with the probability of developing more severe, acute GVHD.^{1109,1110} The infiltrate in GVHD developing after solid organ transplantation is usually brisk in comparison to the more sparse inflammation following bone marrow transplantation.¹¹¹¹ This infiltrate is accompanied by basal vacuolation. Established lesions are characterized by more extensive vacuolation and lymphocytic infiltration of the dermis and scattered,

shrunk, eosinophilic keratinocytes with pyknotic nuclei, at all levels of the epidermis.¹⁰²⁴ These damaged cells are often accompanied by two or more lymphocytes, producing the picture known as 'satellite cell necrosis' (lymphocyte-associated apoptosis) (Fig. 3.22).¹¹¹² Fluorescent *in situ* hybridization analysis for donor lymphocytes in a skin biopsy specimen can serve as an early diagnostic tool for GVHD.¹¹¹³ Follicular wall necrosis was reported in one case.¹⁰⁵¹ These various changes are often graded as to severity.¹¹¹⁴ However, the biopsy findings after bone marrow transplantation correlate poorly with the clinical severity of the skin rash and in predicting progression of the disease to a more severe clinical state.^{1115,1116} Even normal-appearing skin is not necessarily normal on histological examination.¹¹¹⁷ The following scheme has been proposed by Horn:¹¹¹⁸

- Grade 0: Normal skin
- Grade 1: Basal vacuolar change
- Grade 2: Dyskeratotic cells in the epidermis and/or follicle, dermal lymphocytic infiltrate
- Grade 3: Fusion of basilar vacuoles to form clefts and microvesicles
- Grade 4: Separation of epidermis from dermis.

Figure 3.22 (A) Graft-versus-host disease. (B) Lymphocytes are in close apposition to apoptotic keratinocytes. (H&E) (C) Graft-versus-host disease, late-stage lesion. In this example, there is still vacuolar alteration of the basal layer with formation of apoptotic keratinocytes and satellite cell necrosis.

Continued

Figure 3.22, cont'd (D) The underlying dermis shows pronounced thickening of collagen bundles with extension into subcutaneous septa. Appendages are not observed in this section. (H&E) **(E)** Eruption of lymphocyte recovery. There is an upper dermal perivascular infiltrate, with vasodilation, slight exocytosis, and a few apoptotic keratinocytes. (H&E)

Omenn syndrome (OMIM 603554), an autosomal recessive form of severe combined immunodeficiency due to mutations in the *RAG1*, *RAG2*, or *Artemis* genes, presents soon after birth with erythroderma, desquamation, recurrent infections, hepatosplenomegaly, and failure to thrive. B lymphocytes are usually absent, but the T lymphocytes in the peripheral blood that are activated and oligoclonal can cause a GVHD, the reason for its mention here.

The pattern in the early *chronic phase* of GVHD may sometimes even resemble that seen in acute GVHD.¹¹¹⁹ Pigment incontinence may be prominent. A rare manifestation is so-called ‘columnar epidermal necrosis’ characterized by small foci of TEN accompanied by a lichenoid tissue reaction.¹¹²⁰ Immunofluorescence shows a small amount of IgM and C3 in colloid bodies in the papillary dermis and some immunoglobulins on necrotic keratinocytes.^{1069,1070}

In the late *sclerodermoid phase*, there are usually mild epidermal changes such as atrophy and basal vacuolation, although a lichenoid tissue reaction, with satellite cell necrosis, can still be identified (**Fig. 3.22C**). There is thickening of dermal collagen bundles that assume a parallel arrangement. The dermal fibrosis, which may result in atrophy of skin appendages, usually extends into the subcutis, resulting in

septal hyalinization (**Fig. 3.22D**).¹¹⁰⁸ Subepidermal bullae were present in one reported case.¹¹²¹

The immunomodulatory agent roquinimex has produced eccrine sweat gland necrosis in a number of instances.¹¹²²

Although in its infancy, **composite tissue allografts** are being performed with increasing frequency. One such example is the hand allograft. Rejection of allografted skin manifests with changes that are characteristic but not very specific.¹¹²³ An excellent review of this topic was published in 2008 by Kanitakis.¹¹²³ The changes range from mild morbilliform reactions to spongiotic vesiculation, a pseudolymphomatous pattern ± lichenoid changes, and a severe necrotizing (grade IV) pattern.¹¹²³

Electron microscopy

Ultrastructural examination shows ‘satellite cell necrosis’ in both stages with lymphocytes in close contact with occasional keratinocytes,¹¹²⁴ some of which show the changes of apoptosis. The term ‘lymphocyte-associated apoptosis’ is therefore more appropriate than ‘satellite cell necrosis’.¹¹²⁵ Lymphocytes are also in contact with melanocytes¹¹²⁶ and Langerhans cells, the latter being reduced in number.

Melanosomes may be increased in the melanocytes. The late sclerotic phase is distinct from scleroderma, with some apoptotic cells in the epidermis and numerous active fibroblasts in the upper dermis.¹¹²⁷

Differential diagnosis

A microscopic image similar to GVHD is sometimes seen in subacute radiation dermatitis (see p. 614)¹¹²⁸ and in the cutaneous eruption of lymphocyte recovery (see later). There is a lack of specificity in skin biopsy specimens taken in the initial 3 weeks after bone marrow transplantation.¹¹²⁹ Distinction from a drug eruption is also difficult.^{1130–1132} The presence of eosinophils is generally taken to favor a drug reaction, but this is not a correct assumption because eosinophils are occasionally seen in GVHD.¹¹³³ Marra *et al.* highlighted the perils of using skin biopsy specimens to distinguish between drug reactions and cutaneous GVHD.¹¹³⁴ They reported three patients in whom the presence of eosinophils on skin biopsy led to the mistaken diagnosis of a drug reaction, leading to a delay in treatment for their GVHD.¹¹³⁴ Others have questioned the value of skin biopsy in this condition.¹¹³⁵ The presence of more than five apoptotic keratinocytes, predominantly involving adnexal keratinocytes, is said to favor GVHD. Fulminant lesions in the acute stage resemble those seen in TEN with subepidermal clefting and full-thickness epidermal necrosis. Skin biopsies in Omenn syndrome look similar to those in GVHD. However, in Omenn syndrome there is always acanthosis and parakeratosis, whereas in GVHD the epidermis is generally flat, rarely with parakeratosis.¹¹³⁶ Inflammation is more marked in Omenn syndrome.¹¹³⁶ In the early chronic phase of GVHD, the lichenoid lesions closely resemble those of lichen planus, although the infiltrate is not usually as dense.¹¹³⁷ Biopsies taken from follicular papules resemble lichen planopilaris.^{1047,1059} Late-stage lesions resemble *morphea* or *scleroderma*, but the latter conditions are not associated with poikilodermatous surface changes; the only possible exception would be an 'overlap' connective tissue disease combining the features of poikilodermatous lupus erythematosus or dermatomyositis with scleroderma. In other words, a biopsy showing poikiloderma atrophicum vasculare with significant dermal sclerosis should always raise the question of late-stage GVHD. Another issue is so-called 'maturation arrest' or *keratinocyte dysmaturation resulting from certain therapeutic agents* used in treating leukemias and solid tumors, including alkylating agents such as cyclophosphamide, busulfan, and thiotepe and antimetabolites such as cytarabine and etoposide. A similar phenomenon results from the use of pegylated doxorubicin.¹¹³⁸ The microscopic findings produced by these agents include epidermal atrophy, keratinocyte necrosis with scattered apoptotic keratinocytes, vacuolar alteration of the basilar layer, and superficial dermal inflammation – all features of GVHD. Another finding of diagnostic importance is the formation of enlarged keratinocytes with irregularly shaped nuclei and large acidophilic nucleoli; these changes also involve eccrine sweat duct epithelium. This keratinocyte atypia is thought to result from the effects of these drugs on nucleic acids or on normal regulatory functions of the underlying dermis. Due to the overlap in microscopic appearance, Horn *et al.* recommended avoiding areas of identifiable chemotherapy effect when considering a biopsy to rule out GVHD.¹¹³⁹ Note that significant microscopic changes due to chemotherapy can be found even in the face of minimal clinical disease. Cytologic atypia and loss of orderly surface maturation are not criteria for GVHD and when found are suggestive of epidermal dysmaturation due to chemotherapy; nevertheless, the possible coexistence of the two phenomena cannot be completely ruled out.

ERUPTION OF LYMPHOCYTE RECOVERY

The original description of this 'entity' involved patients who developed a maculopapular eruption after receiving cytoreductive therapy

(without bone marrow transplant) for acute myelogenous leukemia.¹¹³⁹ The lesions usually developed 14–21 days later, coincident with the return of lymphocytes to the circulation.¹¹¹⁸ The histological similarities between this eruption and those seen with mild GVHD and with the administration of cyclosporin A (cyclosporine) led to the suggestion that all three conditions represent variations on the theme of lymphocyte recovery.¹¹¹⁸ It has also been proposed that 'autologous GVHD' may in fact represent the eruption of lymphocyte recovery.¹¹⁴⁰

Histopathology

The eruption is characterized by an upper dermal perivascular infiltrate of small T lymphocytes with accompanying vascular dilatation. There is mild exocytosis of lymphocytes with occasional apoptotic keratinocytes. Lymphocytes are sometimes seen in apposition with these degenerate cells ('satellite cell necrosis'). The appearances resemble mild GVHD (Fig. 3.22E).¹¹⁴¹ In one report, Pautrier-like microabscesses containing CD4⁺ cells were present in the epidermis, mimicking mycosis fungoides.¹¹⁴²

The systemic administration of recombinant cytokines prior to marrow recovery leads to a relatively heavy lymphocytic infiltrate with nuclear pleomorphism and hyperchromasia.¹¹⁴³

AIDS INTERFACE DERMATITIS

A lichenoid reaction pattern with interface changes resembling those seen in erythema multiforme or fixed drug eruptions has been reported in some patients with AIDS and in whom the clinical presentation suggested a drug reaction.¹¹⁴⁴ The patients had numerous opportunistic infections, and all had received at least one medication prior to the onset of the rash. It has been suggested that systemic and cutaneous immune abnormalities may be relevant in the pathogenesis.¹¹⁴⁴ There is little justification for the continuation of this diagnosis as a discrete entity.

LUPUS ERYTHEMATOSUS

Lupus erythematosus is a chronic inflammatory disease of unknown etiology that principally affects middle-aged women. It has traditionally been regarded as an immune disorder of connective tissue, along with scleroderma and dermatomyositis. However, a striking feature of cutaneous biopsies is the presence in most cases of the lichenoid reaction pattern (interface dermatitis). It may not be present in tumid forms, in lupus profundus (panniculitis), and in lymphocytic infiltration of the skin, if indeed this is truly a variant of lupus erythematosus.

Three major clinical variants are recognized: chronic discoid lupus erythematosus, which involves only the skin; systemic lupus erythematosus (SLE), which is a multisystem disease; and subacute lupus erythematosus, in which distinct cutaneous lesions are sometimes associated with mild systemic illness.^{1145,1146} Some overlap exists between the histological changes seen in these various clinical subsets.¹¹⁴⁷ There are several less common clinical variants that will be considered after a discussion of the major types.

A recent addition to these subsets is undifferentiated connective tissue disease, also called latent or incomplete lupus, in which signs and symptoms do not fulfill any of the accepted classification criteria for the various named connective tissue diseases.^{1148,1149}

Discoid lupus erythematosus

The typical lesions of discoid lupus erythematosus (DLE) are sharply demarcated, erythematous, scaly patches with follicular plugging. They usually involve the skin of the face, often in a butterfly

distribution on the cheeks and bridge of the nose. The neck, scalp, eyelids,¹¹⁵⁰⁻¹¹⁵³ lips,¹¹⁵⁴ oral mucosa,^{1155,1156} and hands, including the nails,¹¹⁵⁷ are sometimes involved. Oral lesions are most often located on labial mucosa or the vermillion border but are also found on the buccal mucosa; they manifest as white spots, foci of erythema, or ulcers.¹¹⁵⁸ Periorbital localization has been reported.¹¹⁵⁹ There is a female preponderance.¹¹⁶⁰ The lesions may undergo atrophy and scarring. Acneiform pitting scars are a rare presentation of DLE.¹¹⁶¹ Cicatricial alopecia may result from scalp involvement.^{1162,1163} DLE is rare in children.¹¹⁶⁴⁻¹¹⁷⁰ Less than 2% of patients with DLE have an onset before 10 years of age.¹¹⁷¹ Children have a particularly high level of transition to systemic disease.¹¹⁷² Squamous cell carcinoma is a rare complication in any site.¹¹⁷³⁻¹¹⁷⁵ Reflectance confocal microscopy awaits further evaluation as a diagnostic tool for DLE, although it appears to be promising for biopsy site selection.¹¹⁷⁶

A *hypertrophic variant* of DLE in which verrucous lesions develop, usually on the arms, has been reported.¹¹⁷⁷⁻¹¹⁷⁹ Lupus erythematosus hypertrophicus et profundus is a very rare destructive variant of hypertrophic DLE with a verrucous surface and eventual subcutaneous necrosis.¹¹⁸⁰ The face and arms are the most common sites of hypertrophic DLE. Lesions resembling keratoacanthomas may develop.¹¹⁸¹ Verrucous lesions were present in one patient with lupus erythematosus associated with porphyria.¹¹⁸² This variant of lupus erythematosus may be misdiagnosed as squamous cell carcinoma on superficial shave biopsy.¹¹⁸³ Squamous cell carcinoma is an uncommon late complication.¹¹⁷⁹

Annular lesions, resembling erythema multiforme, may rarely develop acutely in patients with all forms of lupus erythematosus.¹¹⁸⁴⁻¹¹⁸⁶ This syndrome, known as **Rowell's syndrome**, is also characterized by a positive test for rheumatoid factor and speckled antinuclear antibodies.^{1184,1187-1192} The antiphospholipid syndrome may also be present.^{1193,1194} Lupus-associated TEN may represent a more severe variant of Rowell's syndrome.¹¹⁹⁵ However, there is some controversy about the existence of this syndrome. Antiga *et al.* reviewed all the reported cases and found that most could be attributed to lupus variants with annular or polycyclic lesions; only a minority of patients actually appeared to have both lupus erythematosus and erythema multiforme, and these occurrences could be considered coincidental.¹¹⁹⁶

Papulonodular lesions associated with diffuse dermal mucin are uncommon manifestations of chronic cutaneous lupus erythematosus.^{1197,1198} They can be quite numerous.¹¹⁹⁹ This mucinosis has presented as periorbital edema.¹²⁰⁰ This variant is part of the spectrum of tumid lupus erythematosus.

Tumid lupus erythematosus (lupus erythematosus tumidus)¹²⁰¹ consists of erythematous, urticaria-like, nonscarring plaques and sometimes papules on the face, neck, and upper trunk. They are usually in sun-exposed areas.^{1202,1203} Monolateral severe eyelid erythema and edema are unique manifestations of this variant.¹²⁰⁴ Lesions may have a fine scale and be pruritic.¹²⁰⁵ It usually occurs in a setting of DLE, but sometimes SLE has been present or rarely develops subsequently.^{1206,1207} Tumid lupus has also developed following the use of highly active antiretroviral therapy (HAART) for HIV infection.¹²⁰⁸ Tumid lupus is part of a spectrum that includes the papulonodular type (discussed previously). A study of 80 patients with this disease concluded that on the basis of specific histopathological features, this condition should be considered a separate entity of cutaneous lupus erythematosus.¹²⁰⁹ There is usually a good response to antimalarials with this form of the disease.¹²⁰²

Lymphocytic infiltration of the skin (of Jessner and Kanof) is now regarded as a variant of DLE,^{1210,1211} although there is still speculation that some cases may represent borreliosis.¹²¹² Although various studies in the 1980s concluded that they were separate entities on the basis of the direct immunofluorescence, the usual absence of epidermal damage, and the phenotype of the infiltrating lymphocytes, recent

studies have suggested that it may be part of the tumid spectrum of DLE. Provocative phototesting gives similar results.¹²¹¹ A comparison of the histopathological and clinical features of this condition and tumid lupus erythematosus showed more similarities than differences, supporting a continuous spectrum of these two conditions.¹²¹³

Linear lesions, often following the lines of Blaschko, have been reported,¹²¹⁴⁻¹²¹⁸ including several examples that have occurred in childhood.^{1219,1220} Many of them have been on the face,¹²²¹⁻¹²²³ although the trunk has also been involved.¹²²⁴ Several cases of a sclerodermiform linear lupus erythematosus have been reported.¹²²⁵ It may represent an unusual mosaicism along Blaschko's lines or the transfer of microchimerisms that mount a chronic graft-versus-host-like reaction.¹²²⁵

Discoid lesions may be seen in up to 20% of individuals with SLE,¹²²⁶ often as a presenting manifestation.¹¹⁶⁸ It is therefore difficult to estimate accurately the incidence of the progression of the discoid to the systemic form. This is on the order of 5–10%¹²²⁷⁻¹²²⁹ and is most likely in those who present abnormal laboratory findings, such as a high titer of antinuclear antibody (ANA) and antibodies to DNA, from the beginning of their illness.¹²³⁰ Approximately 70% of patients possess low titers of anti-Ro/SSA antibodies, and it remains to be seen whether such patients are at greater risk of progression to the systemic form.^{1229,1231,1232} Some patients with localized lesions may progress to more widespread disease.¹²³³ Visceral manifestations are absent in uncomplicated DLE. An increased incidence of various haplotypes has been found;^{1234,1235} HLA-DRB1 alleles are involved in the genetic susceptibility of a Mexican population.¹²³⁶ It has been suggested that genes encoding immunoregulatory molecules may determine individual susceptibility to lupus erythematosus.¹²³⁷ Lesions resembling discoid or subacute lupus erythematosus can be found in the female carriers of X-linked chronic granulomatous disease¹²³⁸⁻¹²⁴³ and, rarely, in an autosomal form of that disease.^{1244,1245} DLE has also been reported in association with Cockayne's syndrome,¹²⁴⁶ with a deficiency of C5,¹²⁴⁷ C2,¹²⁴⁸ and other immunodeficiency syndromes.¹²⁴⁹ A combination of complement deficiency and smoking may be a risk factor for cutaneous lupus erythematosus in men.¹²⁵⁰ It has also been induced by adalimumab,¹²⁵¹ infliximab,¹²⁵² pantoprazole,¹²⁵³ and cyclosporine.¹⁶⁰ Phototesting with UVA or combined UVA and UVB irradiation will produce positive reactions in approximately half of all patients tested.¹²⁵⁴

Dermoscopic analysis may be helpful in the recognition of DLE. Key findings include a perifollicular whitish halo, keratotic plugs, and telangiectasias.¹²⁵⁵ There appears to be excellent correlation between dermoscopic and histopathologic findings.¹²⁵⁵ Preliminary data indicate that anti-annexin 1 antibodies are elevated in the sera of patients with DLE compared to normal controls; detection of these antibodies may prove to be helpful in the diagnosis of this variant of lupus erythematosus.¹²⁵⁶

The inflammatory infiltrate in cutaneous lupus erythematosus is composed of T lymphocytes, with a slight predominance of CD4⁺ over CD8⁺ cells. In DLE, type I IFNs and potentially autoreactive cytotoxic lymphocytes targeting adnexal structures are highly associated with scarring lesions.¹²⁵⁷ There is a strong expression of granzyme B and the type I IFN-induced protein MxA.¹²⁵⁸

Treatments for localized DLE include sunscreens, topical corticosteroids, and occasionally antimalarials or retinoids. Intralesional corticosteroids are helpful in hypertrophic lesions, and tumid lesions respond to antimalarial therapy.¹²⁵⁸ Other therapies include topical calcineurin inhibitors¹²⁵⁹ and newer immunomodulating agents.¹²⁶⁰

Histopathology^{1147,1261}

DLE is characterized by a lichenoid reaction pattern and a superficial and deep dermal infiltrate of inflammatory cells that have a tendency to accumulate around the pilosebaceous follicles (Fig. 3.23). In scalp lesions with scarring alopecia, there is considerable reduction in the size of sebaceous glands and the lymphocytic infiltrate is maximal

Figure 3.23 Discoid lupus erythematosus. The dermal infiltrate is both superficial and deep with perifollicular accentuation. (H&E)

Figure 3.24 Discoid lupus erythematosus. There is more cell death and less vacuolar change in the basal layer than usual. Distinction from the subacute form is difficult in these cases. (H&E)

around the mid-follicle at the level of the sebaceous gland.¹¹⁶² The lichenoid reaction (interface dermatitis) takes the form of vacuolar change ('liquefaction degeneration'), although there are always scattered Civatte bodies (apoptotic keratinocytes). In lesions away from the face, the number of Civatte bodies is always much greater and a few colloid bodies may be found in the papillary dermis (Fig. 3.24). In older lesions, there is progressive thickening of the basement membrane, which is best seen with a PAS stain. Other epidermal changes include hyperkeratosis, keratotic follicular plugging, and some atrophy of the malpighian layer.¹²⁶²

The dermal infiltrate is composed predominantly of lymphocytes with a few macrophages. Atypical lymphocytes, mimicking mycosis fungoides, have been reported in one case.¹²⁶³ Occasionally, there are a few plasma cells, and rarely there are neutrophils and nuclear dust in the superficial dermis in active lesions. Plasma cells are prominent in oral lesions.¹¹⁵⁵ Fibrin extravasation and superficial edema are also seen in the papillary dermis in some early lesions. Mucin is sometimes increased, but only rarely are there massive amounts.¹²⁶⁴ Amyloid of keratinocyte origin¹²⁶⁵ and calcification have been reported on a few occasions.^{1266,1267}

In *tumid lesions*, there is increased dermal mucin in all cases, often accompanied by subepidermal edema (Fig. 3.25). Some cases have only a sparse inflammatory cell infiltrate, whereas others have a heavy infiltrate of lymphocytes and less mucin.¹²⁶⁸ A few scattered neutrophils may be present. Epidermal involvement is uncommon;^{1205,1269} in one study of 80 cases, epidermal atrophy and alterations at the dermoepidermal junction were absent in all cases.¹²⁰⁹ In a blinded comparison of tumid lupus and Jessner's lymphocytic infiltrate, there were only slight differences between the two.¹²¹³ Slight epidermal atrophy and focal thickening of the dermoepidermal junction were more common in tumid lupus and the lymphocytic infiltrate was less dense in tumid lupus than in Jessner's lymphocytic infiltrate, supporting a continuous spectrum for these two disorders.¹²¹³ A pattern resembling that seen in tumid lupus erythematosus has been reported at the injection site of IFN.¹²⁷⁰ There was abundant dermal mucin in addition to the heavy lymphocytic infiltrate along hair follicles with vacuolar change of the basal layer of the follicles.¹²⁷⁰ A similar, but less severe, reaction has since been reported.¹²⁷¹

In *hypertrophic lesions*, there is prominent hyperkeratosis and epidermal hyperplasia. There may be a vague resemblance to a superficial squamous cell carcinoma, particularly on shave biopsy.^{1272,1273} Elastic fibers are often present between epidermal cells at the tips of the epidermal downgrowths. Transepidermal elimination of these fibers also occurs.¹¹⁷⁹

Direct immunofluorescence of involved skin in discoid lupus will show the deposition of immunoglobulins, particularly IgG and IgM, along the basement membrane zone in 50–90% of cases (Fig. 3.26).^{1274–1280} The incidence is less than 50% in the author's experience; perhaps this is a reflection of subtropical cases in Caucasians or the prompt biopsy of younger lesions (see p. 70). Complement components are present less frequently. This so-called 'lupus band test' is positive much less often in lesions from the trunk.¹²⁸¹ A positive lupus band test should always be interpreted in conjunction with the clinical and histological findings¹²⁸² because it may be obtained in chronic light-exposed skin¹²⁸³ and some other conditions.¹²⁸⁴ Cytoid bodies, sometimes perifollicular in location, are present in more than half the cases.¹²⁸⁵

Electron microscopy

There is some disorganization of the basal layer, scattered apoptotic keratinocytes, and reduplication of the basement membrane.¹¹⁷⁸ Indeterminate cells, dendritic macrophages, and unusual dendritic cells with short and blunt dendrites have been reported in the dermis.¹²⁸⁶

Subacute lupus erythematosus

Subacute lupus erythematosus is characterized by recurring, photosensitive, nonscarring lesions that may be annular or papulosquamous in type.^{1287–1289} They are widely distributed on the face, neck, upper trunk, and extensor surfaces of the arms.¹²⁹⁰ A case with only acral lesions has been reported.¹²⁹¹ In another case, arcuate plantar plaques were followed by a facial lesion.¹²⁹² The patients frequently have a mild systemic illness with musculoskeletal complaints and serological abnormalities but no central nervous system disease.^{1293,1294} Renal disease occurred in 16% of patients in one series.¹²⁹⁵ Severe visceral involvement is most uncommon.¹²⁹⁶ Cases with overlap features between the systemic and subacute forms have been reported.^{1297–1299} Rare clinical presentations have included erythroderma,^{1300,1301} erythroderma and bullae,¹³⁰² bullae alone,^{1303,1304} toxic epidermal necrolysis-like,¹³⁰⁵ a poikilodermatous pattern,¹³⁰⁶ pityriasiform lesions,¹³⁰⁷ onset in childhood,^{1308,1309} the simultaneous occurrence of Sweet's syndrome,¹³¹⁰ and an association with the ingestion of thiazide,¹³¹¹ terbinafine,^{1312–1316} etanercept,¹³¹⁷ infliximab,¹³¹⁸ leflunomide,^{1319,1320} bupropion,¹³²¹ phenytoin,¹³²² adalimumab,¹³²³ simvastatin,¹³²⁴ efalizumab,¹³²⁵ capecitabine,¹³²⁶ ticlopidine,¹³²⁶ anastrozole,¹³²⁷ antihistamines,¹³²⁸ calcium channel blockers,¹³²⁹ griseofulvin,¹³³⁰ omeperazole,^{1331–1333} golimumab,¹³³⁴ citalopram,¹³³⁵

Figure 3.25 Discoid lupus of tumid type. (A) There is a superficial and deep dermal infiltrate. (H&E) (B) Dermal mucin is greatly increased. (Alcian blue) (C) Another case that might have been called Jessner's lymphocytic infiltrate in the past. (H&E)

doxycycline,¹³³⁶ lansoprazole,¹³³⁷ doxorubicin with or without cyclophosphamide,^{1338,1339} systemic fluorouracil,¹³⁴⁰ and esomeprazole.¹³⁴¹ It has also been induced by radiation therapy,¹³⁴² radioiodine treatment,¹³⁴³ topical imiquimod used in the treatment of actinic keratoses,¹³⁴⁴ and contact with fertilizer- and pesticide-containing hay.¹³⁴⁵ It has followed the inhalation of tiotropium bromide, a bronchodilator.¹³⁴⁶ It has been

reported in patients with hepatocellular carcinoma,¹³⁴⁷ prostate carcinoma,¹³⁴⁸ epidermoid carcinoma of the lung,¹³⁴⁹ and adenocarcinoma *in situ* of the esophagus.¹³⁵⁰ An interesting finding is that smokers with cutaneous lupus erythematosus are less responsive to antimalarial treatment than non-smokers.¹³⁵¹ Drugs causing subacute lupus erythematosus are listed in [Table 3.5](#).

Figure 3.26 Discoid lupus erythematosus. A broad band of C3 is present along the basement membrane zone. (Direct immunofluorescence)

The test for ANA is often negative if mouse liver is used as the test substrate but positive if human Hep-2 cells are used.¹³⁵² There is a high incidence of the anticytoplasmic antibody Ro/SSA,^{1353–1358} it is found in a higher incidence in those with annular rather than papulosquamous lesions.¹³⁵⁹ This antibody is also found in SLE, neonatal lupus erythematosus, in the lupus-like syndrome that may accompany homozygous C2 deficiency,^{1360–1363} and in Sjögren's syndrome.^{1364,1365} The Ro/SSA antigen is now known to be localized in the epidermis, and it is thought that antibodies to this antigen are important in the initiation of tissue damage.¹³⁶⁶ Antigen expression is higher in photosensitive forms of lupus erythematosus.¹³⁶⁷ However, the antibody titer does not correlate with the activity of the skin disease.¹³⁶⁸ Regarding the management of subacute lupus erythematosus, a drug etiology should first be excluded and any potential culprit drugs should be ceased. Depigmentation and other cosmetic concerns of the patient should also be addressed. Treatments that have been used include topical or systemic corticosteroids; antimalarials such as hydroxychloroquine sulfate and thalidomide;¹³⁶⁹ topical immunomodulators such as tacrolimus and pimecrolimus; leflunomide;¹³⁷⁰ mycophenolate mofetil;¹³⁷¹ salbutamol cream;¹³⁷² and efalizumab (the monoclonal antibody to CD11a).¹³⁷³

Histopathology¹³⁷⁴

The histopathological features differ only in degree from those seen in discoid lupus.^{1293,1375} Usually, there is more basal vacuolar change, epidermal atrophy, and dermal edema and superficial mucin than in discoid lupus, but there is less hyperkeratosis, pilosebaceous atrophy, follicular plugging, basement membrane thickening, and cellular infiltrate (Fig. 3.27).^{1374–1377} The pattern can be characterized as a pauci-inflammatory, vacuolar, lymphocytic interface dermatitis.¹²⁶⁸ Apoptotic keratinocytes (Civatte bodies) are sometimes quite prominent in subacute lupus erythematosus; they may be found at various levels within the epidermis, resembling erythema multiforme (Fig. 3.28).^{1378,1379} Furthermore, the infiltrate is usually confined more to the upper dermis than in discoid lupus.^{1374,1380} The previously mentioned features relate to the more common annular form, which may resemble erythema multiforme to varying degrees.¹¹⁹² The papulosquamous form of subacute lupus erythematosus has no distinguishing features to permit differentiation from the discoid form.¹³⁷⁶ The toxic epidermal necrolysis-like variant of subacute lupus erythematosus shows full-thickness epidermal necrosis in addition to a

Figure 3.27 (A) Subacute lupus erythematosus. **(B)** There is patchy basal vacuolar change and occasional Civatte bodies. (H&E)

Figure 3.28 Subacute lupus erythematosus. The infiltrate extends into the lower epidermis, and cell death occurs at a slightly higher level than usual. This variant can be mistaken for erythema multiforme. (H&E)

sparse superficial lymphocytic infiltrate and changes of interface dermatitis.¹³⁸¹ A review of the literature failed to reveal significant histopathologic differences between idiopathic and drug-induced subacute lupus erythematosus.¹³⁸² In particular, tissue eosinophilia has not been shown to be a differentiating feature between these two variants.¹³⁸³

The lupus band test (discussed previously) shows immunoglobulins at the dermoepidermal junction in approximately 60% of cases. The band is usually not as thick or as intensely staining as in DLE. Very fine, dust-like particles of IgG (a speckled pattern) have been described predominantly, but not exclusively, in the cytoplasm of basal cells^{1380,1384–1386} and also in the cellular infiltrate in the dermis.¹³⁸⁷ This pattern is not specific for subacute cutaneous lupus erythematosus or the presence of Ro/SSA antibodies. Dust-like particles were found in only 3% of cases in one study.¹³⁸⁸

Systemic lupus erythematosus

In SLE, the changes in the skin are part of a much more widespread disorder. Four clinical manifestations are particularly important as criteria for the diagnosis of SLE: skin lesions, renal involvement, joint involvement, and serositis.¹¹⁴⁵ The coexistence of the first two of these manifestations is sufficient to justify a strong presumption of the diagnosis.

Cutaneous lesions take the form of erythematous, slightly indurated patches with only a little scale. They are most common on the face, particularly the malar areas. The lesions are usually more extensive and less well-defined than those of DLE and devoid of atrophy. Scarring is an important complication of all forms of lupus erythematosus.¹³⁸⁹ The lesions may spread to the chest and other parts of the body. In some instances, they may be urticarial,¹³⁹⁰ bullous,^{1391–1393} follicular,¹³⁹⁴ mucinous,¹³⁹⁵ purpuric, or, rarely, ulcerated. Facial edema is another presentation.¹³⁹⁶ Ichthyosiform skin changes have been described in an SLE/scleroderma overlap disorder.¹³⁹⁷ It is important to remember that skin lesions do not develop at all in approximately 20% of patients with SLE; approximately the same proportion have discoid lesions of the type seen in chronic DLE, but usually without scarring.¹³⁹⁸ This latter group often has less severe disease.^{1226,1399} Subclinical inflammatory alopecia has also been reported.¹⁴⁰⁰ A spectrum of elastic tissue changes can occur in patients with lupus erythematosus. They range from mid-dermal elastolysis to anetoderma (see p. 396). Cutaneous infections associated with SLE have included aspergillosis, phaeohyphomycosis, and atypical mycobacteriosis;^{1401–1403} the latter in particular can mimic true cutaneous lesions of lupus erythematosus.¹⁴⁰³

The digits, calves, and heels are involved in the rare **chilblain (pernio)** **lupus**, which results from microvascular injury in the course of SLE.^{1404–1406} A verrucous form of chilblain lupus has been reported in an adult.¹⁴⁰⁷ Red lunulae have been reported in association with chilblain lupus and also as an isolated phenomenon in SLE.^{1408–1410} Familial chilblain lupus (OMIM 610448) is due to a mutation in the *TREX1* gene on chromosome 3p21. It is allelic to Aicardi-Goutières syndrome (OMIM 225750), a rare genetic leukoencephalopathy.¹⁴¹¹

SLE may coexist with other diseases, such as rheumatoid arthritis, scleroderma,¹⁴¹² dermatomyositis, Sjögren's syndrome (sometimes with associated annular erythema),¹⁴¹³ eosinophilic fasciitis,¹⁴¹⁴ autoimmune thyroiditis,¹⁴¹⁵ ulcerative colitis,¹⁴¹⁶ myasthenia gravis,¹⁴¹⁷ pemphigus,¹⁴¹⁷ gout,¹⁴¹⁸ alopecia areata,¹⁴¹⁹ sarcoidosis,¹⁴²⁰ porphyria cutanea tarda,^{1421,1422} Sweet's syndrome,¹⁴²³ psoriasis,¹⁴²⁴ pyodermitis vegetans,¹⁴²⁵ cutaneous T-cell lymphoma,¹⁴²⁶ dermatitis herpetiformis,¹⁴²⁷ acanthosis nigricans,¹⁴⁴⁵ and various complement deficiencies.^{1428–1432} Its relationship to Kikuchi's disease (necrotizing histiocytic lymphadenopathy) remains a mystery. Patients with Kikuchi's disease should be followed up long-term for the possible development of SLE.^{1433–1435} Mycosis fungoides may masquerade as cutaneous lupus erythemato-

sus.¹⁴³⁶ It has been suggested that some patients with photosensitive lupus erythematosus represent the coexistence of a photodermatosis such as polymorphic light eruption.¹⁴³⁷ In a study from Sweden, where the overall prevalence of the latter disease is relatively high, 42% of 260 consecutive SLE patients had a history of polymorphic light eruption.¹⁴³⁸ Many of these associated conditions represent the chance coexistence of the two diseases, although the occurrence of SLE with diseases such as scleroderma, dermatomyositis, and rheumatoid arthritis has been included in the concept of mixed connective disease, an ill-defined condition with various overlap features and the presence of ribonucleoprotein antibody (see p. 354).^{1439,1440}

Joint symptoms, serositis, and renal disease are frequent.¹¹⁴⁵ Lymphocytopenia is common and correlates with the presence of autoantibodies targeting nuclear antigens.^{1441,1442} It is also a highly sensitive marker of systemic involvement but with low specificity.¹⁴⁴³ Rare manifestations include vegetations on the valve leaflets in the heart, vasculitis,^{1444,1445} diffuse pulmonary interstitial fibrosis, hemophagocytic syndrome,¹⁴⁴⁶ laryngeal lesions,¹⁴⁴⁷ mucosal involvement,^{1156,1448} peripheral neuropathy, and ocular involvement.¹¹⁴⁵ Neurological manifestations are not uncommon, and occasionally these are thromboembolic in nature, related to the presence of circulating anticardiolipin antibodies (the 'lupus anticoagulant') (see p. 225).^{1449–1451} Cutaneous infarction^{1452–1454} and ulceration¹⁴⁵⁵ are other rare manifestations of this circulating antibody. However, digital necrosis can occur in patients with SLE in the absence of this antiphospholipid syndrome.¹⁴⁵⁶

SLE usually runs a chronic course with a series of remissions and exacerbations. The most common causes of death are renal failure and vascular lesions of the central nervous system.¹⁴⁵⁷ Infection is another mode of death, usually related to immunosuppression.¹⁴⁵⁸ The 10-year survival rate currently exceeds 90%.¹¹⁴⁵ In a review of 57 children with SLE, 8 had died – 6 from severe infection and 2 from renal failure.¹⁴⁵⁹

Investigations

Various laboratory investigations are undertaken in the diagnostic study of patients with suspected lupus erythematosus.^{1460–1462} The LE cell preparation is now of historical interest only, and it has been replaced as a screening test by the immunofluorescent detection of circulating ANA.¹⁴⁶³ The presence of LE bodies *in vivo* may have some diagnostic value.¹⁴⁶⁴ Various patterns of immunofluorescence, corresponding to different circulating antibodies, can be seen; the incidence of positivity depends on the substrate used.¹⁴⁶⁵ A homogeneous staining pattern is usually obtained. This test is positive in more than 90% of untreated patients, with many of the negative cases belonging to the subset with anti-Ro/SSA antibodies (see p. 67). One study found that patients with SLE and positive ANA had a significantly higher frequency of renal disorders than those with negative ANA.¹⁴⁶⁶

Much more specific for the diagnosis is the detection of antibodies to double-stranded DNA. They are found in more than 50% of cases, and the titer may be used to monitor the progress of treatment.¹¹⁴⁵ The presence of these antibodies is often associated with renal disease. They are usually detected by a radioimmunoassay method.

Other antibodies may also be detected, including rheumatoid factor and antibodies to extractable nuclear antigen (ENA)¹²³² and Ro60.¹⁴⁶⁷ Anti- α -fodrin antibodies, commonly found in patients with Sjögren's syndrome, are seen in a small number of patients with SLE.¹⁴⁶⁸ Antineutrophil cytoplasmic antibodies (ANCA) have been present in many patients with minocycline-induced lupus-like syndrome.¹⁴⁶⁹ They may also be present in other cases of SLE.¹⁴⁷⁰ False-positive serological tests for syphilis are sometimes present.¹¹⁴⁵ Antibodies to cytoplasmic keratin proteins in the epidermis have been detected in patients with SLE. Their presence appears to correlate with the finding of cytoplasmic deposits of immunoglobulin in epidermal keratinocytes.^{1471,1472} Antibodies to basement membrane antigens

are sometimes found in the sera of patients with no evidence of bullous lesions.¹⁴⁷³

Etiology

Altered immunity, drugs, viruses, genetic predisposition, hormones, and ultraviolet light may all contribute to the etiology and pathogenesis of lupus erythematosus.¹¹⁴⁵ Immunological abnormalities are a key feature. Various autoantibodies are often present, and high levels of antibodies against double-stranded DNA have been considered specific for SLE. Immune complexes are found in approximately 50% of affected individuals,¹²²⁷ and those containing DNA appear to be responsible for renal injury. Vascular injury may result from the deposition of these complexes.¹⁴⁷⁴ The link between the lupus band and the pathogenesis remains controversial because immunoglobulins and complement components, including the membrane attack complex (MAC), can be found in both lesional and nonlesional skin of patients with SLE.¹⁴⁷⁵ CD59 (protectin) is expressed in nonlesional skin (and not in normal controls) in which complement activation has occurred. CD59 acts specifically to inhibit the terminal pathway of complement by blocking the formation of MAC. Although some MAC is found in nonlesional skin, as already stated, it seems that CD59 expression keeps this in check.¹⁴⁷⁵ There have been conflicting reports on the role of the various T-cell subsets.^{1476–1478} However, CD4 $\alpha\beta$ T cells infiltrate the papillary dermis and appear to play some role in the basal damage.¹⁴⁷⁹ There is a slight predominance of CD4⁺ over CD8⁺ cells. Increased cytokine production, particularly IFN- γ , has been noted;^{1480,1481} overexpression of a variety of cytokines has also been found in keratinocytes from SLE patients.¹⁴⁸² The skin of patients with active SLE has shown increased expression of LL-37 (cathelicidin, also elevated in acne rosacea) and plasmacytoid dendritic cells as well as IFN- α ; the role of these molecules in the pathogenesis of SLE will likely be the subject of future studies.¹⁴⁸³ Increased cytokine production appears to be responsible in DLE.¹⁴⁸⁴ Infiltrating lymphocytes carrying CXCL10 in their granules might amplify the lesional inflammation and be responsible for the chronic course of this disease.¹⁴⁸¹ It appears that dysregulation of T lymphocytes causes the activation of B cells, producing various autoantibodies of pathogenetic significance.¹⁴⁸⁵ Interestingly, a chimeric CD4-monoclonal antibody has been used successfully in the treatment of severe cutaneous lupus erythematosus.¹⁴⁸⁶ Other immunological findings include a reduction in epidermal Langerhans cells, loss of HLA-DR surface antigens on dermal capillaries, and a small percentage of Leu8⁺ cells in the dermal infiltrate.^{1477,1487,1488} HLA-DR is expressed on epidermal keratinocytes, while ICAM-1 is expressed on keratinocytes, dermal inflammatory cells, and endothelial cells.¹⁴⁸⁸

Matrix metalloproteinases, which contribute to tissue destruction, regeneration, inflammation, and apoptosis, are abundantly expressed by keratinocytes in all major forms of cutaneous lupus erythematosus.¹⁴⁸⁹ In particular, MMP-3, -10, -19, and -26 are overexpressed while MMP-7 is detected in keratinocytes in regions of edema and vacuolization.¹⁴⁸⁹

There is evidence that a DNA binding protein, high mobility group box 1 (HMGB1), may enhance inflammation in SLE and promote the development of cutaneous lesions. This molecule binds to other molecules released from apoptotic cells (nucleosomes, DNA), increasing their immunogenicity and promoting their uptake by macrophages through the receptor for advanced glycation end products (RAGE) and certain toll-like receptors (TLRs). Inflammation accompanies this process.¹⁴⁹⁰

In a small but important proportion of cases, the onset of systemic lupus is quite clearly related to the ingestion of drugs.¹¹⁴⁵ Those incriminated include procainamide,¹⁴⁹¹ isoniazid, hydralazine,¹⁴⁹² quinidine,¹⁴⁹³ minocycline,^{1494–1498} penicillamine,¹⁴⁹⁹ sulfonamides,¹⁵⁰⁰ rifampicin,¹⁵⁰¹ terbinafine,^{1502,1503} chlorpromazine,¹⁵⁰⁴ phenylbutazone, etanercept,¹⁵⁰⁵

hydrochlorothiazide,¹⁵⁰⁶ methimazole,^{1507,1508} carbamazepine,^{1509,1510} atenolol,¹⁵¹¹ practolol, phenobarbital, and phenytoin. A review also lists allopurinol, captopril, clonidine, danazol, ethosuximide, griseofulvin, lithium, lovastatin, mesalazine, methyldopa, penicillin, piroxicam, primidone, propylthiouracil, streptomycin, thiamazole, trimethadione, and valproate.¹⁴⁶² A new anti-angiogenesis drug (COL-3) used in the treatment of cancer can also induce SLE.¹⁵¹² Oral contraceptives may sometimes result in a flare-up of the disease. Withdrawal of the drug is usually followed by slow resolution of the process. Exposure to insecticides has also been incriminated.^{1513,1514} Procainamide-induced SLE, which is the best studied of the drug-related cases, has a low incidence of renal involvement.¹¹⁴⁵ High titers of leukocyte-specific ANA are present in those with clinical disease.¹⁵¹⁵

A subset of drug-induced lupus erythematosus is characterized primarily by cutaneous disease and the usual presence of anti-Ro/SSA antibodies. The most common drugs associated with this disease are antihypertensive drugs, hydrochlorothiazide, calcium channel blockers, ACE inhibitors, griseofulvin, and terbinafine.¹⁵¹⁶ A study published in 2007 concluded that long-term exposure to statins may be associated with drug-induced lupus erythematosus and other autoimmune disorders.¹⁵¹⁷ Fatal cases have been reported despite early drug discontinuation and aggressive systemic immunosuppressive therapy.¹⁵¹⁷ Antihistone antibodies are also found in drug-induced lupus.^{1518,1519}

The role of viruses is still controversial. Structures resembling parvovirus have been demonstrated on electron microscopy, particularly in endothelial cells, in SLE, and also in DLE.¹⁵²⁰ There is doubt about the nature of these inclusions. Rare cases associated with parvovirus B19, and with HIV infection, have been reported.^{1268,1521} Epstein-Barr virus has also been incriminated.¹⁵²²

Familial cases have been recorded, usually in siblings but also in successive generations. The disease has been observed in numerous pairs of identical twins. Several HLA types have been incriminated;^{1523,1524} one of these is found on chromosome 6p21.¹⁵²⁵ One study showed an association between SLE and numerous genes, some with known immune-related functions.¹⁵²⁵ They include *IRF5* on chromosome 7q32, *ITGAM* on 16p11.2, *KIAA1542* on 11p15.5, and *PXK* on 3p14.3.¹⁵²⁵ A novel single-nucleotide polymorphism of the Fc γ receptor IIIa gene is associated with genetic susceptibility to SLE in Chinese populations.¹⁵²⁶

The role of sunlight in inducing and exacerbating cutaneous lupus of all types is well documented.^{1527–1530} Ultraviolet (UV)-B irradiation is the most frequent inducer of skin lesions in photosensitive lupus, although very high doses of UVA may trigger lesions in some patients.^{1254,1531} If an extended phototesting protocol is used, almost all patients with lupus erythematosus have evidence of aberrant photosensitivity.¹⁵³² The mechanism of action appears to be the stimulation of keratinocytes to translocate cytoplasmic and nuclear antigens, such as SSA and SSB. Ultraviolet irradiation also stimulates keratinocytes and fibroblasts to release cytokines, such as TNF- α and IL-1 α . A rare allele (-308A, TNF2) of the *TNF- α* promoter gene is strongly linked to subacute lupus erythematosus.¹⁵³¹ Sunlight-induced damage of cellular DNA contributes ultimately to the formation of immune complexes that may be of pathogenetic significance.

Finally, the occurrence of both systemic and subacute lupus erythematosus in association with cancer, albeit rarely, raises the possibility of a paraneoplastic association.^{785,1533,1534}

To assist in the evaluation of clinical therapeutic trials, the Cutaneous Lupus Erythematosus Disease Area and Severity Index was developed.¹⁵³⁵ It is a useful tool for measuring clinical response. Cutaneous lesions are usually treated in the same way that skin lesions in the subacute form are managed. Photoprotection may also be required.¹⁵³² There is one report of a patient with vasculitis in SLE who responded to rituximab after failing to respond to mycophenolate mofetil, high-dose methylprednisolone, and intravenous immunoglobulin.¹⁴⁴⁵

Figure 3.29 Acute lupus erythematosus. There is thickening of the basement membrane zone as well as vacuolar change and Civatte bodies. (H&E)

Histopathology¹¹⁴⁷

The cutaneous lesions of SLE show prominent vacuolar change involving the basal layer. Civatte body formation is not usually a feature. Edema, small hemorrhages, and a mild infiltrate of inflammatory cells, principally lymphocytes, are present in the upper dermis. Eosinophils may be present in drug-induced cases and in urticarial lesions. Flame figures were present in one urticarial case.¹⁵³⁶ Fibrinoid material is deposited in the dermis around capillary blood vessels, on collagen, and in the interstitium. It sometimes contributes to thickening of the basement membrane zone (Fig. 3.29). The main constituents of this thickened zone are type IV and type VII collagen.¹⁵³⁷ Mucin can be demonstrated by special stains,¹⁵³⁸ and its presence may be helpful in distinguishing the lesions of SLE from polymorphic light eruption.¹⁵³⁹ The term ‘cutaneous lupus mucinosis’ has been used for cases with abundant dermal mucin.¹⁵³⁵ A vasculitis, usually of leukocytoclastic type, is sometimes present. It may be complicated by thrombosis. Extravascular necrotizing palisaded granulomas, as originally described in Churg–Strauss syndrome, were present in one case.¹⁵⁴⁰

The subset of patients who have antibodies to Ro/SSA show additional vascular changes not usually seen in those without these antibodies. They include telangiectasia, endothelial cell necrosis, and luminal deposits of fibrin.¹²⁶⁸

In *follicular lupus erythematosus*, the interface changes are localized to the follicular infundibulum.¹³⁹⁴ Perivascular inflammation is present, allowing a distinction from lichen planopilaris.

In *chilblain lupus*, a lichenoid (vacuolar interface) reaction overlies a lymphocytic vasculitis involving both superficial and deep plexuses.

In *mucosal lupus*, which affects predominantly the lips and buccal mucosa, a lichenoid mucositis with a band-like and deeper perivascular infiltrate of lymphocytes and some plasma cells is present.¹⁴⁴⁸ The cytokeratin profile is that of hyperproliferative epithelium with the expression of CK5/6 and CK14 in all epithelial layers, CK16 in the suprabasal layer, and CK10 in the prickle cells.¹⁴⁴⁸

Neutrophils are sometimes present in the upper dermis in nonbullous cases.¹⁵⁴¹ They are much less frequent than is seen in Sweet’s syndrome, except the very early stages of that disease. They are both perivascular and interstitial with leukocytoclasia (Fig. 3.30).¹⁵⁴¹ None of the patients progressed to bullous lupus erythematosus. Pincus, McCalmont, and LeBoit reported five patients with SLE and unusual neutrophilic infiltrates.¹⁵⁴² There were some similarities in different cases to urticaria (but the infiltrate was too heavy), Sweet’s syndrome (but the infiltrate was confined to the papillary dermis and lacked

Figure 3.30 Neutrophilic lupus erythematosus. These lesions presented as erythematous palmar nodules. Subepidermal clefting is noted, but bullae did not develop in these lesions. (H&E)

edema), and palisaded neutrophilic and granulomatous disease (but the changes were in the papillary dermis).¹⁵⁴² A similar finding has also been reported in neonatal lupus erythematosus.¹⁵⁴³

Hematoxyphile bodies – altered nuclei that are the tissue equivalent of the LE cells in the blood – are found rarely in the skin, in contrast to visceral lesions in which they are not infrequent.

There are an increasing number of reports of Kikuchi’s disease (histiocytic necrotizing lymphadenitis) among patients with SLE; the coexistence of these two processes is associated with both flares of SLE and relatively frequent cutaneous involvement.¹⁵⁴⁴

The incidence of a positive lupus band test will depend on the site biopsied¹⁵⁴⁵ and the duration of the lesion biopsied. Lesions should be of 2 or 3 months’ duration. Involved skin is positive in almost 100% of cases, whereas uninvolved skin from sun-exposed areas is positive in approximately 90% of cases.¹⁵⁴⁶ Biopsies of uninvolved skin from sun-protected areas are positive in only one-third of cases. Positive tests are obtained from sun-exposed skin in one-third or more of normal controls,^{1547–1549} although the staining pattern is usually weak.¹⁵⁴⁷ There is a marked predominance of IgM ± C3.¹⁵⁵⁰ IgG3 is the predominant subclass of IgG deposited.¹⁵⁵¹ The lupus band test colocalizes with collagen VII.¹⁵⁵² Circulating basement membrane zone antibodies may participate in the formation of the lupus band.¹⁵⁵³ The lupus band test may be negative in remissions, early lesions, treated lesions, and some cases of drug-induced lupus erythematosus.¹⁵⁵⁴ It is also negative in UV-induced skin lesions, although their histopathological features are similar to those of primary lupus erythematosus of the different subtypes.¹²⁵⁴ The test is useful in excluding diseases that are clinically similar to SLE.¹⁵⁵⁵ MAC is deposited in a granular pattern along the basement membrane zone in approximately 75% of patients with cutaneous lupus erythematosus.¹⁵⁵⁶ It is also found in subacute lupus erythematosus.¹⁵⁵⁷ It may be a useful adjunct to the lupus band test.¹⁵⁵⁶ Another finding on direct immunofluorescence is epidermal nuclear staining, usually for IgG. It is found in only a small percentage of cases, but it may correlate with oral involvement (Fig. 3.31).¹⁵⁵⁸ Immunoelectron microscopy has shown that the immunoglobulin deposits are predominantly in the papillary dermis, just beneath the basal lamina.¹⁵⁵⁹ The deposition appears to damage both type IV and type VII collagen.¹⁵⁶⁰ DNA is a major component of the complexes.

Figure 3.31 Lupus erythematosus, direct immunofluorescence. This biopsy shows epidermal nuclear IgG staining, an infrequent but diagnostically helpful finding.

Differential diagnosis

A major consideration in the differential diagnosis of forms of lupus erythematosus with interface change is *lichen planus*. Ordinary lichen planus has a distinctive set of findings that include hyperkeratosis, hypergranulosis that is often wedge-shaped, broad acanthosis, vacuolar alteration of the basilar layer producing a 'sawtoothed' appearance of the epidermal base, numerous apoptotic keratinocytes near the junctional zone, and a band-like infiltrate that appears to 'hug' the epidermis and obscures the dermal–epidermal junction. However, a number of these features are also identified in forms of LE – particularly hyperkeratosis, vacuolar alteration of the basilar layer, and formation of apoptotic keratinocytes. Occasional examples of LE show a hypertrophic epidermis, which combined with the other changes can create a close resemblance to *hypertrophic lichen planus*. Lesions of *lichen planopilaris*, particularly in scalp biopsies, can be problematic because they may display follicular plugging, a dense perifollicular infiltrate, and, in later stages, marked thinning of lateral follicular walls. Some cases with mixed features of lichen planus and cutaneous LE cannot be readily categorized and may require serial biopsies and long-term follow-up before a diagnosis can be firmly established. However, features that would tend to favor cutaneous LE include epidermal atrophy, a patchy and sometimes superficial and deep perivascular and periappendageal infiltrate, inflammation involving eccrine sweat coils, significant dermal mucin deposition, and sometimes evidence for panniculitis not directly associated with perifollicular inflammation. Direct immunofluorescence study can be helpful in that a 'lupus band' is not identified in lichen planus, but instead there is a combination of clustered Civatte bodies in the papillary dermis staining positively for IgM and fibrin deposition along the dermal–epidermal junction. The finding of an elevated ANA titer on routine testing, or of a positive ANA with direct cutaneous immunofluorescence, would lend further support to the diagnosis of cutaneous LE.

Lupus erythematosus can resemble other connective tissue diseases, particularly *dermatomyositis* and *morphea/scleroderma*. Systemic LE

and (sometimes) subacute cutaneous LE can show a close microscopic resemblance to *dermatomyositis*. Both can show epidermal atrophy, vacuolar alteration of the basilar layer, and significant interstitial mucin deposition. Later, a band-like subepidermal infiltrate can develop, producing the image of *poikiloderma atrophicans vasculare*. Changes of hyperkeratosis, follicular plugging, or a periadnexal component to the dermal infiltrate would tend to favor LE. Ordinarily, direct immunofluorescence would be considered decisive because only LE would be expected to have a band of immunoglobulin along the dermal–epidermal junction. However, false-negative studies are not unusual in LE, while according to one study, a small proportion of dermatomyositis cases can show a positive band test with staining for IgM, IgG, or C3.¹⁵⁶¹ The significance of the latter finding, however, could be questioned because granular IgM and/or C3 deposition can be found in normal sun-exposed skin, particularly facial skin. Studies suggest that plasmacytoid dendritic cells may play a role in the pathogenesis of both LE and dermatomyositis. McNiff and Kaplan¹⁵⁶² found that distribution of these cells, as labeled by CD123, is different in the two disorders: preferentially located within the epidermis in dermatomyositis but mainly in the dermis in LE. It is possible that the differing localization of these cells might be useful in the microscopic differential diagnosis of these two conditions. The histopathologist should consider several possible scenarios when faced with such a problematic biopsy: the lesion may represent only LE, only dermatomyositis, mixed connective tissue disease, or a less well-defined overlap connective tissue disorder. Lesions of LE with overlapping features of *scleroderma/morphea* are not as common but have been reported, particularly in an unusual linear variant of LE.¹⁵⁶³

Changes of *poikiloderma atrophicans vasculare* can also create diagnostic dilemmas. With onset early in life, lesions of congenital LE could show a close microscopic resemblance to those of *poikiloderma congenitale* (the *Rothmond–Thomson syndrome*) or *congenital telangiectatic erythema* (*Bloom's syndrome*). Clinical and serologic findings and direct immunofluorescence studies would be needed to rule out these other uncommon syndromes. As an acquired dermatosis, changes of *poikiloderma atrophicans vasculare* can be seen in early, *patch stage mycosis fungoides* as well as in LE and dermatomyositis. The distribution of lesions would ordinarily be quite different in poikilodermatous mycosis fungoides, particularly when compared to poikilodermatous LE, which would be concentrated in sun-exposed sites. Although cytologic atypia among lymphocytes is often minimal in this stage of mycosis fungoides, finding lymphocytes with cerebriform nuclei, lining up along the basilar layer or migrating into the epidermis in the absence of spongiosis ('exocytosis without spongiosis') would be features of concern for mycosis fungoides, whereas interstitial dermal mucin deposition and superficial and deep perivascular and periadnexal inflammation would favor a diagnosis of LE.

Lupus erythematosus also falls into the same differential diagnosis as a miscellaneous group of disorders characterized by superficial and deep dermal infiltrates, including secondary syphilis, polymorphic light eruption, lymphoma or 'pseudolymphoma' (lymphocytoma cutis, lymphadenosis benigna cutis), and lymphocytic infiltration of Jessner. The latter lesion is now widely considered a form of tumid lupus erythematosus. Therefore, the main diagnostic difficulty now lies in determining whether or not these tumid lesions truly fit within the lupus erythematosus spectrum.

A lichenoid tissue reaction pattern can certainly occur in secondary syphilis; in addition, perifollicular infiltrates can be identified and may even be a prominent finding in syphilitic alopecia (*moth-eaten alopecia*). On the other hand, plasma cells are more likely to be present than in LE, and certainly numerous plasma cells would be unexpected in LE (with the possible exception of lupus panniculitis). Inflammatory infiltrates in syphilis often tightly surround dermal vessels (*coat-sleeving* of vessels) while at the same time perieccrine inflammation is not a hallmark of this disease. Increased interstitial

mucin deposition is also a helpful discriminating feature because this would be more commonly encountered in LE. Definitive diagnosis is made possible by the finding of spirochetes in tissue with silver stains (e.g., Warthin–Starry or Steiner and Steiner stains) or with immunohistochemistry using newer monoclonal antibodies. Direct immunofluorescence with positive basement membrane immunoglobulin deposition would obviously favor LE. Serologic methods would be of additional help, as long as one remains aware of the possibility of biologic false-positive VDRL or FTA-ABS studies in some cases of LE.

As is the case in LE, *polymorphic light eruption* is a photosensitive disorder that often first manifests in the spring with some diminution of intensity as the summer wears on. The clinical and microscopic findings can vary. However, in our view, interface dermatitis with significant vacuolar alteration of the basilar layer is not a feature of most examples of polymorphic light eruption, and the hyperkeratosis, follicular plugging, and basement membrane zone thickening seen in some forms of LE do not occur. Pronounced dermal edema is often seen in polymorphic light eruption, but this is not generally accompanied by significant mucin deposition. Inflammatory infiltrates are primarily targeted toward vessels; inflammation adjacent to adnexa can be seen, but in contrast to LE, infiltration of these structures is not observed and vacuolar alteration of basilar outer root sheath epithelium is not a feature. Direct immunofluorescence study and serologic testing can be definitive in difficult cases.

Dense, superficial, and deep dermal infiltrates can be seen in discoid LE but also in *lymphoma* and *lymphocytoma cutis*. In some instances, cutaneous LE can also feature lymphoid follicle-like structures with germinal center formation, whereas interstitial dermal mucin can sometimes be found in cutaneous lymphomas. The typical epidermal changes of LE are generally not seen in these other disorders; however, lupus-like epidermal and dermal changes can sometimes be observed in panniculitic T-cell lymphoma, which often bears a striking resemblance to lupus panniculitis. See Chapter 17 for further information on this subject. Adnexal infiltration is not a feature of B-cell lymphomas. A folliculotropic T-cell lymphoma exists, but infiltration involving the full thickness of follicular epithelia is usually observed, sometimes with intrafollicular Pautrier microabscess formation or changes of follicular mucinosis. In LE, infiltrates are usually confined to the follicular-stromal interface and associated with vacuolar alteration of basilar outer root sheath epithelium and often with thinning of lateral follicular walls. Secondary follicular mucinosis has been reported in LE but is distinctly uncommon.

Lesions of tumid lupus, including those that may have received the designation lymphocytic infiltrate of Jessner or reticular erythematous mucinosis, typically lack the epidermal changes ordinarily associated with lupus erythematosus. Therefore, the varying combinations of atrophy, vacuolar alteration of the basilar layer, hyperkeratosis, or follicular plugging expected in other forms of LE are not observed. As a result, one is generally dependent on the constellation of dermal findings: perivascular and periadnexal lymphocytic infiltrates and interstitial dermal mucin deposition. The differential diagnosis of such lesions includes some conditions previously mentioned, including polymorphic light eruption and, occasionally, lymphoma or lymphocytoma cutis. Additional disorders that might be considered include *erythema annulare centrifugum*, featuring superficial and deep, ‘coat-sleeved’ inflammatory infiltrates; *chronic urticaria*, characterized by edema and a superficial and deep perivascular infiltrate of mild to moderate intensity; and *scleredema*, in which there is marked thickening of the dermis due to interstitial deposits of mucin. However, *erythema annulare centrifugum* lacks significant dermal mucin deposition or periadnexal inflammation, and it may show some degree of overlying parakeratosis and spongiosis. Chronic urticaria is edematous but not mucinous, and *targeted* periadnexal inflammation is not a feature (occasionally, perivascular inflammation involving vessels near appendages may be confused with true periadnexal

infiltration). Scleredema does show significant mucin deposition, but inflammation is typically sparse.

Finally, the marked acanthosis seen in some examples of hypertrophic LE can raise concerns for *squamous cell carcinoma*, and in fact carcinoma can develop in long-standing lesions of cutaneous LE. As in other similar circumstances, careful evaluation for malignant features (infiltration of connective tissue stroma, nuclear pleomorphism, cell necrosis, and bizarre mitotic figures) is essential in distinguishing true squamous cell carcinoma from pseudoepitheliomatous hyperplasia. This may be a difficult task when small biopsies with sectioning or staining artifacts are submitted for evaluation; in these circumstances, submission of a larger specimen may provide the best solution.

LUPUS ERYTHEMATOSUS VARIANTS

The traditional variants of lupus erythematosus (discoid, subacute, and systemic) have already been discussed. This section covers uncommon, but distinct, clinicopathological variants.

Neonatal lupus erythematosus

Neonatal lupus erythematosus is a rare syndrome^{1564–1568} characterized by a transient lupus dermatitis developing in the neonatal period accompanied by a variety of hematological and systemic abnormalities,^{1569,1570} including congenital heart block.^{1571,1572} Congenital presentation is rare.¹⁵⁷³ Cutaneous lesions resemble those seen in subacute cutaneous lupus erythematosus;¹⁵⁷⁴ telangiectatic macules may be a feature.^{1575,1576} Cutis marmorata telangiectatica congenita-like lesions have been reported in a number of patients; in most papers describing this phenomenon, it is reported to be a transient feature.¹⁵⁷⁷ Periorbital, scalp, and extremity lesions are common.¹⁵⁷⁸ Papules on the plantar surface of both feet are a rare presentation.¹⁵⁷⁹ So too is a presentation mimicking Langerhans cell histiocytosis.¹⁵⁸⁰ Depigmented lesions are rare;¹⁵⁸¹ so too are cutaneous erosions¹⁵⁸² and lupus panniculitis.¹⁵⁸³ Approximately 20% of the mothers have SLE at the time of the birth, and a similar percentage will subsequently develop it.¹⁵⁷¹ Various factors have been proposed to explain clinical disease in the fetus in the absence of disease in the mother.¹⁵⁸⁴ Other mothers may have Sjögren’s syndrome or, uncommonly, a vasculitis.¹⁵⁸⁵ The Ro/SSA antibody is present in infants and mothers in nearly all cases,^{1578,1586–1589} and it has been suggested that this is of maternal origin and crosses the placenta, where it is subsequently destroyed by the infant.^{1590,1591} Fetal tissue injury as reflected in heart block or endocardial fibroelastosis may be more dependent on elevated levels of Ro antibodies than on the mere presence of these antibodies.¹⁵⁹² Antibodies to α -fodrin,¹⁵⁹³ La/SSB, and U₁RNP have been detected in some cases.^{1594–1598} The anticardiolipin antibody has been reported in an infant with neonatal lupus erythematosus.¹⁵⁹⁹ Successive siblings may be affected with this condition.^{1600,1601} Persistent scarring, atrophy, and depigmentation may result.¹⁶⁰²

The histological features resemble those seen in subacute lupus erythematosus.¹⁶⁰³ Perivascular and periadnexal infiltrates without epidermal changes have been described, and targetoid lesions with interstitial infiltrates of neutrophils and leukocytoclasia have also been reported (Fig. 3.32).¹⁶⁰⁴

Bullous lupus erythematosus

A rare form of SLE, bullous lupus erythematosus is a skin eruption that clinically and histologically closely resembles dermatitis herpetiformis.^{1605–1608} Rare clinical variants include a localized linear form¹⁶⁰⁹ and one in which milia develop.¹⁶¹⁰ The blisters are subepidermal with neutrophils in the papillary dermis and some lymphocytes around vessels in the superficial plexus (Fig. 3.33).¹⁶¹¹ Bullae have been

Figure 3.32. Neonatal lupus erythematosus. The findings are quite similar to those in subacute lupus erythematosus and include epidermal atrophy, vacuolar alteration of the basal layer, and superficial dermal mucin deposition. This particular lesion has more prominent follicular plugging than sometimes observed in this lupus variant. (H&E)

Figure 3.33 Bullous lupus erythematosus. There is a subepidermal blister, beneath which is a band-like neutrophilic infiltrate. (H&E)

reported in a case of DLE¹⁶¹² and also following steroid withdrawal in SLE.¹³⁹³ The antiphospholipid syndrome is a rare association.¹⁶¹³ Linear or mixed linear and granular deposits of IgG are found along the basement membrane zone.¹⁶¹⁴ IgA and/or IgM may also be present.^{1615–1617} The immunoreactants are deposited beneath the lamina densa,¹⁶¹¹ and they are accordingly on the dermal side of salt-split skin.¹⁶¹⁸ Electron microscopy confirms that the split is below the lamina densa.¹⁶¹⁹

There appear to be at least two immunologically distinct subtypes characterized by the presence or absence of circulating and/or tissue-bound autoantibodies to type VII collagen.^{1616,1620–1622} Patients with autoantibodies to type VII collagen are similar but not identical to patients with epidermolysis bullosa acquisita (see p. 163).¹⁶²³ The autoantibodies appear to recognize the same noncollagenous (NC1) domain.¹⁶²⁴ In other cases, various components of the basement membrane zone may be targeted. In one case, there were autoantibodies to the bullous pemphigoid antigen (BP230, BPAg1), laminin-5, laminin-6,

and type VII collagen.¹⁶²⁵ In another case, the autoantibodies were to BPAg1 alone.¹⁶²⁶

Bullous systemic lupus erythematosus is treated with dapsone, corticosteroids, and other immunosuppressive agents. The response to dapsone is often dramatic and supports its use as first-line therapy for this condition.¹⁶¹⁹ Antimalarials can also be used, but patients with concurrent porphyria cutanea tarda may exhibit a toxic response.¹²⁵⁸

Lupus panniculitis

Lupus panniculitis (lupus profundus) presents clinically as firm subcutaneous inflammatory nodules, from 1 to 4 cm or more in diameter, situated on the head, neck, arms, abdominal wall, thighs, or buttocks.^{1627,1628} There is a greater frequency of periorbital edema as the initial manifestation of lupus profundus in black South Africans compared to other published series.¹⁶²⁹ There are isolated reports of breast involvement (lupus mastitis)^{1630–1632} and also of linear lesions.¹⁶³³ Rare cases have been reported in childhood.¹¹⁷¹ Lupus panniculitis is a rare complication that may precede the development of overt systemic or discoid lupus erythematosus.¹⁶³⁴ A patient with widespread lesions in the setting of a partial deficiency of C4 has been reported.¹⁶³⁵ In some cases, the lesions subside without any other sign of the disease.¹⁶³⁶ The clinical diagnosis may be difficult if there are no other manifestations of lupus erythematosus. The lesions may be misdiagnosed as deep morphea.¹⁶³⁷ Lupus panniculitis is discussed in more detail with the panniculitides (see Chapter 17). Lupus panniculitis may be responsive to antimalarials.¹²⁵⁸

DERMATOMYOSITIS

Dermatomyositis is characterized by the coexistence of a nonsuppurative myositis (polymyositis) and inflammatory changes in the skin.^{1638–1642} Cutaneous lesions may precede the development of muscle involvement by up to 2 years or more.^{1643–1645} Cases without muscle involvement (amyopathic dermatomyositis and dermatomyositis sine myositis) exist.^{1646–1652} Amyopathic dermatomyositis is defined as the finding of dermatomyositis in the absence of any clinical or laboratory signs of muscle disease for at least 6 months (formerly 2 years) after the onset of skin pathology.^{1653,1654} It accounts for 10–20% of the total population of dermatomyositis patients seen in referral clinics in the United States.¹⁶⁵⁴ There is a strong association between amyopathic dermatomyositis and nasopharyngeal carcinoma in China.¹⁶⁵⁵ Its association with familial polyposis coli was probably fortuitous.¹⁶⁵⁶ An 'adermatopathic' variant of dermatomyositis has also been postulated.¹⁶⁵⁴

Dermatomyositis may occur in either sex and at any age. Those cases commencing in childhood are sometimes considered as a separate clinical group (juvenile dermatomyositis) because of the greater incidence in them of multiorgan disease.^{1657–1661} Rarely, this includes a necrotizing vasculitis that may involve the gut and other organs, with a fatal outcome.¹⁶⁵⁷ The initial physical and laboratory findings in patients with juvenile dermatomyositis may be nonspecific. Instead of the heliotrope rash and Gottron's papules classically associated with dermatomyositis (see below), there may be a nonspecific extremity rash, periungual erythema, and sometimes pruritus.¹⁶⁶² An amyopathic variant also occurs.¹⁶⁶³ Vasculopathy does not seem to occur in this amyopathic form of juvenile dermatomyositis.¹⁶⁶³ Other manifestations of juvenile dermatomyositis include lipoatrophy, generalized hypertrichosis, and infrapatellar hypertrichosis.¹⁶⁶⁴ Associations include the 22q11.2 deletion syndrome.¹⁶⁶⁵

The skin lesions in adult dermatomyositis are violaceous or erythematous, slightly scaly lesions with a predisposition for the face, shoulders, the extensor surfaces of the forearms, and the thighs.¹⁶⁶⁶ Poikilodermatous features (telangiectasia, hyperpigmentation, and

hypopigmentation) may be seen.¹⁶⁶⁷ Photosensitivity is sometimes present.¹⁶⁶⁸ Pruritus is not uncommon, but it has not been highlighted in the literature.¹⁶⁶⁹ Other characteristic findings are nail fold changes, gingival telangiectases,¹⁶⁷⁰ purplish discoloration and edema of the periorbital tissues (heliotrope rash), and atrophic papules or plaques over the knuckles (Gottron's papules).¹⁶⁶⁷ Plaques of calcification sometimes develop.^{1671,1672} Unusual presentations include severe periorbital edema,¹⁶⁷³ an isolated flagellate eruption on the back,¹⁶⁷⁴⁻¹⁶⁷⁶ a plaque-like mucinosis,^{1677,1678} the presence of follicular keratotic papules with some features of pityriasis rubra pilaris,¹⁶⁷⁹⁻¹⁶⁸² lesions resembling malignant atrophic papulosis,¹⁶⁸³ a panniculitis,^{1684,1685} stasis dermatitis,¹⁶⁸⁶ erythroderma,^{1687,1688} or vesiculobullous eruption.¹⁶⁸⁹ A patient with vesiculobullous disease and a panniculitis but without muscle disease has been reported.¹⁶⁹⁰ In another patient with acute-onset vesiculobullous dermatomyositis, massive mucosal necrosis of the intestines occurred.¹⁶⁹¹ A Dermatomyositis Skin Severity Index has been developed and validated.¹⁶⁹² This will allow a comparison of various treatment modalities in future clinical trials.

Other clinical features include the presence of proximal muscle weakness and elevation of certain serum enzymes such as creatine phosphokinase.^{1666,1693} Muscle ultrasound is sometimes abnormal in patients with dermatomyositis and normal muscle enzyme levels.¹⁶⁹⁴ Raynaud's phenomenon, dysphagia, Sjögren's syndrome, morphea profunda,¹⁶⁹⁵ retinopathy, and overlap features with scleroderma^{1696,1697} and with lupus erythematosus sometimes occur.^{1667,1698} Interstitial lung disease is an uncommon but debilitating complication that is usually associated with the presence of the anti-Jo-1 antibody.¹⁶⁹⁹⁻¹⁷⁰³ Digital infarcts showing microangiopathy may occur in patients with severe pulmonary disease.¹⁷⁰⁴ Other autoantibodies, such as to histone and Ro/SS-A, are sometimes present.^{1705,1706}

An underlying malignancy is present in 10% or more of cases.¹⁷⁰⁷⁻¹⁷¹⁷ In one series, the prevalence of malignancy was high (23%).¹⁶⁷⁶ Predictive factors for malignancy include male gender, older age of onset, the presence of dysphagia, and the absence of interstitial lung disease.¹⁷¹⁸⁻¹⁷²⁰ Although the malignancies have spanned nearly every organ in the body, specific variants published in recent years have included nasopharyngeal carcinoma,^{1721,1722} ovarian cancers,^{1712,1713,1723} melanoma,¹⁷²⁴ breast cancer,¹⁷²² squamous cell carcinoma of the penis,¹⁷²⁵ transitional cell carcinoma of the bladder,^{1715,1726} lymphoma,¹⁷²⁷ myeloma,¹⁷¹⁷ and cancers of the esophagus,¹⁷²⁸ lung, stomach, and colon.¹⁷²⁹ The cutaneous manifestations may precede the diagnosis of the malignancy by up to 1 year or more. Amyopathic cases of paraneoplastic dermatomyositis have been reported.¹⁷³⁰ Dermatomyositis occurring in patients with stage IV melanoma has a poor prognosis.^{1731,1732} Subepidermal vesiculation is an uncommon finding in dermatomyositis; its presence may be related to the occurrence of an internal malignancy, but not necessarily in all cases.^{1689,1733,1734} Bullous pemphigoid has also been recorded as a coexisting disease.¹⁷³⁵

A dermatomyositis-like syndrome has been associated with certain viral illnesses, including parvovirus B19,¹⁷³⁶ toxoplasmosis,¹⁷³⁷ and leishmaniasis.¹⁷³⁸ It has followed administration of hydroxyurea,¹⁷³⁹⁻¹⁷⁴⁹ omeprazole,¹⁷⁵⁰ carbimazole,¹⁷⁵¹ terbinafine,¹⁷⁵² tegafur, IFN- α , BCG vaccination, the various statins,¹⁷⁵² cyclophosphamide,¹⁷⁵³ etoposide,¹⁷⁵³ a herbal medicine,¹⁷⁵⁴ penicillamine,¹⁶⁶⁶ and zoledronic acid.¹⁷⁵⁵ A heliotrope-like eruption mimicking dermatomyositis occurred in a patient receiving imatinib mesylate.¹⁷⁵⁶ Dermatomyositis, including the amyopathic form, has developed in pregnancy, with rapid improvement following delivery^{1757,1758} and in the postpartum period.¹⁷⁵⁹ It has been reported in a patient with hereditary complement (C9) deficiency¹⁷⁶⁰ and in a patient with chronic graft-versus-host disease.¹⁷⁶¹ Cytoplasmic inclusions resembling the paramyxovirus-like structures seen in lupus erythematosus (see p. 69) have also been found in blood vessels in cases of dermatomyositis.¹⁷⁶²

The etiology and pathogenesis are unknown, but immunological mechanisms are certainly involved. In addition to the various

autoantibodies that are often present, activated T cells and natural killer cells have been demonstrated in biopsied muscle.¹⁶⁶⁶ In the skin, the infiltrate consists predominantly of macrophages expressing HLA-DR and of T cells, especially of the CD4 subset.¹⁷⁶³ Plasmacytoid dendritic cells (bone marrow-derived dendritic cells with an ability to secrete large amounts of IFN- α *in vivo* after appropriate stimulation, including viral infection) are present in the skin.¹⁵⁶² These cells, which stain with CD123, play a central role in the pathogenesis of lupus erythematosus,¹⁵⁶² but in contrast to lupus erythematosus in which they are found in the dermis, in dermatomyositis there is a preferential epidermal localization.¹⁵⁶² The deposition of MAC has been demonstrated along the dermoepidermal junction and in some dermal blood vessels.¹⁷⁶⁴ Endothelial cell injury may play an important role in producing some of its clinical manifestations, including lung disease.¹⁷⁶⁵ There are elevated levels of soluble vascular cell adhesion molecule-1 (sVCAM-1).¹⁷⁶⁶ There are abundant levels of angiopoietin-like protein 2 in keratinocytes from cutaneous lesions of dermatomyositis; this substance may contribute to the chronic inflammatory process in skin.¹⁷⁶⁷ There is increasing evidence that a type I IFN-driven immune response and the recruitment of potentially autoreactive T cells via IP10/CXCR3 interaction are involved in the pathogenesis of dermatomyositis skin lesions.¹⁷⁶⁸⁻¹⁷⁷⁰ Plasmacytoid dendritic cells appear to be an important source of these type I IFNs.¹⁷⁷⁰ IL-27 levels are elevated in dermatomyositis and polymyositis patients and are associated with high creatine kinase levels and interstitial lung disease.¹⁷⁷¹

Spontaneous remission without therapy is rare in dermatomyositis.¹⁷⁷² Although there are no double-blind randomized trials, oral corticosteroids are generally considered the primary therapy for dermatomyositis with muscle disease.^{1772,1773} Other therapies include antimalarials, methotrexate, azathioprine, chlorambucin, cyclosporine, cyclophosphamide, mycophenolate mofetil, leflunomide (as a steroid-sparing agent), and intravenous immunoglobulin.¹⁷⁷⁴⁻¹⁷⁷⁶ Therapy using anti-TNF- α drugs has been tried with variable results. Tamoxifen, which also has anti-TNF- α effect, has been successful in a few cases.¹⁷⁷⁷ Rituximab, a monoclonal anti-CD20 antibody, has also been used.¹⁷⁷⁸ Its effect on muscle disease may be better than on skin disease.¹⁷⁷⁹ The treatment of amyopathic juvenile dermatomyositis is controversial; some adopt a conservative approach, whereas others treat aggressively with immunosuppressive agents (prednisone and methotrexate) in an attempt to minimize the risk of progression to myositis.¹⁶⁶³ One study showed that aggressive treatment resulted in improved outcome and a decreased incidence of calcinosis.¹⁷⁸⁰

Histopathology¹⁷⁸¹

The histological changes are quite variable. At times, the changes are subtle (**Fig. 3.34**), with only a sparse superficial perivascular infiltrate of lymphocytes, associated with variable edema and mucinous change in the upper dermis.¹⁷⁸¹ More often, there are the features of a lichenoid tissue reaction consisting of vacuolar change in the basal layer. Only occasional apoptotic keratinocytes are present, if any (**Fig. 3.35**). A few neutrophils are sometimes present in the infiltrate, particularly in those cases with fibrinoid material in the papillary dermis and around superficial vessels. Diffuse dermal neutrophilia and leukocytoclastic vasculitis are rare findings.^{1782,1783} The basement membrane is often thickened. These appearances are indistinguishable from those of acute lupus erythematosus.

At other times, there are additional features of epidermal atrophy, melanin incontinence, and dilatation of superficial vessels (poikiloderma changes).¹⁷⁰⁹ A mild sclerodermoid tissue reaction of variable depth is sometimes present. This may be a consequence of microvascular injury. Lung disease is usually present in these cases.¹⁷⁶⁵ A biopsy from a Gottron's papule will show mild hyperkeratosis and some acanthosis, in addition to the basal vacuolar change (**Fig. 3.35B**).¹⁷⁸⁴ Mucin deposition is present in nearly 40% of cases. The changes are

Figure 3.34 Dermatomyositis. The changes are quite subtle with mild basal vacuolar change and several colloid bodies in the papillary dermis. The appearances may be indistinguishable from acute lupus erythematosus, although in the latter disease basement membrane thickening may be more pronounced and colloid bodies less frequent than in dermatomyositis. (H&E)

similar to those observed in dermatomyositis at other cutaneous sites.¹⁷⁸⁵

Fasciitis, in the form of infiltrates around small vessels, is a feature in dermatomyositis and may even predominate over inflammatory changes in muscle in early stages of the disease.¹⁷⁸⁶ Unusual findings include subepidermal vesiculation, a lobular panniculitis, and dystrophic calcification.^{1684,1685,1787–1789} The vesicular lesions are cell poor with abundant edema fluid. Necrosis of the roof sometimes occurs. An osteogenic sarcoma developed in an area of heterotopic ossification in one case of dermatomyositis.¹⁷⁹⁰

In the Wong type of dermatomyositis, in which pityriasis rubra pilaris-like lesions are present, there is follicular hyperkeratosis with destruction of hair follicles. Cornoid lamellation has been seen in one of these cases.¹⁶⁸¹

Intercellular deposits of immunoglobulins have been reported in the epidermis of nail fold biopsies.¹⁷⁹¹ Colloid bodies containing IgM are sometimes quite prominent in the papillary dermis. The lupus band test is usually negative, although it was positive in a significant number of cases in one series.¹⁷⁹² Vascular deposits of C5b–9 are found in dermatomyositis but not in lupus erythematosus.¹⁷⁹³ Immunoglobulins, including IgA, have been reported in muscle biopsies in dermatomyositis.¹⁷⁹⁴

Differential diagnosis

The microscopic resemblance of poikilodermatous lesions of dermatomyositis to those of lupus erythematosus was discussed previously in the section on lupus erythematosus. It must be acknowledged that the lesions can be sufficiently similar that distinction on histopathologic grounds can be impossible; additional clinical and serologic data would then be essential to reach a correct diagnosis. Also note that combinations of both conditions can be encountered in mixed connective tissue disease and other, less well-defined overlap disorders. When present, hyperkeratosis, follicular plugging, periadnexal infiltrates, and vacuolar alteration of outer root sheath epithelia with thinning of lateral follicular walls would point to a diagnosis of LE. Direct immunofluorescence study can be helpful in that findings of a 'lupus band' strongly favor LE, whereas deposition of C5b–9 (the membrane attack complex) in vessels and along the dermal–epidermal junction is most characteristic of dermatomyositis. In the study by Magro and Crowson, the best statistical predictor of dermatomyositis was the combination of a

Figure 3.35 Dermatomyositis. (A) The lichenoid reaction pattern is more obvious in this case. The appearances are indistinguishable from cutaneous lupus erythematosus. (H&E) **(B)** Dermatomyositis; Gottron's papule. In addition to the typical features of dermatomyositis, this lesion features hyperkeratosis and irregular acanthosis. (H&E)

negative lupus band test, vascular C5b–9 deposition, and serologic studies showing negative antibodies to Ro, La, Sm (Smith antigen), and RNP.¹⁷⁹³

POIKILODERMAS

The poikilodermas are a heterogeneous group of dermatoses characterized clinically by erythema, mottled pigmentation, and, later, epidermal atrophy. These changes result from basal vacuolar change with consequent melanin incontinence and variable telangiectasia of blood vessels in the superficial dermis (Fig. 3.36). For this reason, Pinkus included the poikilodermatous pattern as a subgroup of the lichenoid tissue reaction.¹

Four distinct groups of poikilodermatous dermatoses are found:

1. The genodermatoses poikiloderma congenitale (Rothmund–Thomson syndrome), congenital telangiectatic erythema (Bloom's syndrome), and dyskeratosis congenita
2. A stage in the evolution of early mycosis fungoides

Figure 3.36 The poikilodermatous reaction pattern in a case of mycosis fungoides. (H&E)

3. A variant of dermatomyositis and less frequently of SLE
4. A miscellaneous group that may follow radiation, cold and heat injury, prolonged exposure to sunlight (poikiloderma of Civatte), and ingestion of drugs (arsenicals and busulfan) or that may occur in the evolution of chronic graft-versus-host reaction.¹⁷⁹⁵

The three genodermatoses mentioned here are distinct clinical entities, but the poikiloderma that may precede mycosis fungoides (poikiloderma atrophicum vasculare) is now regarded as an early stage in the evolution of mycosis fungoides.¹⁷⁹⁶ Likewise, poikilodermatomyositis represents a clinicopathological variant of dermatomyositis rather than a disease *sui generis*. Poikiloderma of Civatte is a controversial entity. It is considered briefly later.^{1797,1798}

POIKILODERMA CONGENITALE (ROTHMUND–THOMSON SYNDROME)

More than 250 cases of poikiloderma congenitale (Rothmund–Thomson syndrome; OMIM 268400) have been reported in the English literature.^{1799,1800} It is an autosomal recessive, genomic instability syndrome. It is a multisystem disorder that affects principally the skin, eyes, and skeletal system.^{1801–1807} There is a predisposition to malignancy.¹⁸⁰⁸ A reticular erythematous eruption commences in the first year of life, and this is followed by the development of areas of hypo/hyperpigmentation. Warty keratoses may appear on the hands, elbows, knees, and feet. Other clinical features include a short stature, cataracts, hypogonadism, mental retardation, photosensitivity to ultraviolet A radiation,^{1799,1809} and, rarely, the development of skin cancers^{1810,1811} including melanoma,¹⁸¹² hematological malignancies¹⁸¹³ including myelodysplasia,^{1814–1816} and osteogenic sarcoma.^{1817,1818} Sometimes only a few of these features are present in an individual case, illustrating the variable presentation of this syndrome.¹⁸¹⁹ Late onset has also been recorded.¹⁸²⁰ Reduced DNA repair capacity might be related to the photosensitivity in early childhood.¹⁸²¹ There appears to be instability in chromosome 8, sometimes leading to trisomy 8 or other abnormalities.¹⁸¹⁹ The condition appears to be genetically heterogeneous. Mutations in the *RECQL4* helicase gene that maps to chromosome 8q24.3¹⁸²² are present in approximately 60% of cases.¹⁸¹² This gene encodes a RecQ DNA helicase.¹⁸⁰⁸ It appears to have a role in the initiation of DNA replication and in sister chromatid adhesion,¹⁸⁰⁸ and it may play a role in telomere maintenance.¹⁸²³ The *RECQL4* gene has also been associated with two other diseases – the Baller–Gerold syndrome

Figure 3.37 Rothmund–Thomson syndrome. This is an example of a warty lesion, showing (in this case) slight hyperkeratosis, acanthosis, and occasional apoptotic keratinocytes. Slight vacuolar alteration of the basal layer is also observed. (H&E)

(OMIM 218600) and RAPADILINO syndrome (RADial hypoplasia/aplasia, PATellar hypoplasia/aplasia, cleft or highly arched PALate, DIarrhea, DISlocated joints, LIttle size, LIMb malformations, and slender NOse and NOrmal intelligence; OMIM 266280). They appear to be allelic with different phenotypic expressions. Poikilodermatous features are usually absent in this latter variant,¹⁸²⁴ but they have been recorded in the Baller–Gerold syndrome, in which craniosynostosis, radial ray defects, and growth retardation are present.

Histopathology

There are the usual poikilodermatous features of hyperkeratosis, epidermal atrophy, basal vacuolar change, rare apoptotic keratinocytes in the basal layer, numerous telangiectatic vessels, scattered dermal melanophages, and a variable upper dermal inflammatory cell infiltrate.¹⁸²⁰

The keratotic (warty) lesions show hyperkeratosis, a normal or thickened epidermis, and some loss of cell polarity, with dyskeratotic cells also present (Fig. 3.37).¹⁸⁰¹ Granulomatous skin lesions were reported to complicate varicella infection in a child with Rothmund–Thomson syndrome and immune deficiency.¹⁸²⁵

Hereditary sclerosing poikiloderma

Hereditary sclerosing poikiloderma (of Weary) (OMIM 173700) is an autosomal dominant disorder with many similar clinical features.¹⁸²⁶ However, there are linear hyperkeratotic and sclerotic bands in the flexural areas, sclerosis of the palms and soles, and clubbing of the nails.¹⁸²⁷ A report from Korea described the microscopic findings from a poikilodermatous lesion: increased basilar melanin, dense sclerotic collagen with telangiectasia in the upper dermis, and fragmented elastic fibers identifiable with elastic tissue staining.¹⁸²⁸

KINDLER'S SYNDROME

Kindler's syndrome (OMIM 173650) is a rare autosomal recessive genodermatosis characterized by acral trauma-induced blistering that improves with age and by progressive poikiloderma in later life.¹⁸²⁹ There are variable degrees of photosensitivity beginning in childhood.¹⁸³⁰ Other clinical features include webbing of the fingers and toes, nail dystrophy, long thick cuticles and mottled pigmentation,¹⁸³¹ pitted palmoplantar keratoderma,¹⁸³² periodontal disease, phimosis,¹⁸³³

esophageal and anal strictures, and gastrointestinal erosions.^{1829,1834–1837} Clinical heterogeneity is well recognized.^{1838,1839} Kindler's syndrome is included as a category of epidermolysis bullosa in the new classification of this disease (see Chapter 6).

Kindler's syndrome is due to a loss-of-function mutation in the *KIND1* gene, also known as C20orf42.¹⁸³⁷ The gene encodes a protein called kindlin-1 that is involved in linking the actin cytoskeleton to integrin-associated platforms in the extracellular matrix.^{1840,1841} It is mainly found in keratinocytes. Loss of kindlin-1 leads to decreased cell adhesion, reduced proliferation of keratinocytes, and increased apoptosis.¹⁸³⁸ Kindler's syndrome is the first inherited disorder that has been found to result from primary defects in the actin cytoskeleton/focal contacts.¹⁸³⁸ More than 25 different mutations have so far been described in *KIND1*, but they do not provide an explanation for the clinical heterogeneity of this disease.^{1838,1840,1842,1843} Furthermore, *KIND1* gene expression and kindlin-1 protein labeling are not always reduced in this syndrome.¹⁸⁴⁴

Some cases are initially misdiagnosed as dystrophic epidermolysis bullosa, but there is no mutation in *COL7A1*.^{1845,1846} Kindler's syndrome was initially thought to represent the association of poikiloderma congenitale with dystrophic epidermolysis bullosa.^{1847–1850} Similar cases have been reported under the title *hereditary acrokeratotic poikiloderma*.^{1851,1852}

Histopathology

There is mild hyperkeratosis, epidermal atrophy, and basal vacuolar change. Rare apoptotic keratinocytes are present in the lower epidermis. There is some telangiectasia and scattered dermal melanophages. There is usually only a sparse superficial dermal infiltrate of lymphocytes.

The bullae in Kindler's syndrome are subepidermal and cell poor, although ultrastructural studies have shown that the split can occur at several levels within the dermoepidermal junction zone, including within the basal cells.^{1851,1853–1855} There is also extensive reduplication of the lamina densa.^{1833,1856,1857}

CONGENITAL TELANGIECTATIC ERYTHEMA (BLOOM'S SYNDROME)

Congenital telangiectatic erythema (OMIM 210900) is a rare autosomal recessive disorder usually known by the eponymous designation Bloom's syndrome. In addition to the telangiectatic, sun-sensitive facial rash, there is stunted growth, proneness to respiratory and gastrointestinal infections, chromosomal abnormalities, and a variety of congenital malformations.^{1858–1860} The facial rash has lupus-like qualities.¹⁸⁶¹ Various chromosomal breakages are found in cultured lymphocytes, the most characteristic being a high rate of sister chromatid exchanges during metaphase.¹⁸⁶² As a consequence, there is a significant tendency to develop various malignancies,¹⁸⁶³ particularly acute leukemia and lymphoma.^{1858,1864} The gene responsible, *RECQ3*, has been mapped to chromosome 15q26.1.¹⁸⁶⁰ Other RECQ helicase defects are

found in Werner's syndrome (a defect in *RECQ2*) and Rothmund–Thomson syndrome (*RECQL4*).

Histopathology

The facial rash consistently shows dilatation of dermal capillaries. There is usually only a mild perivascular infiltrate of lymphocytes. Basal vacuolar change may occur but does not usually result in pigment incontinence.

DYSKERATOSIS CONGENITA

Dyskeratosis congenita is a rare, sometimes fatal genodermatosis characterized primarily by the triad of reticulate hyperpigmentation, nail dystrophy, and leukokeratosis of mucous membranes.^{1865–1867} Other less constant features include a Fanconi-type pancytopenia,^{1868–1870} eye and dental changes, mental deficiency, deafness,¹⁸⁷¹ intracranial calcification,¹⁸⁷² palmoplantar hyperkeratosis, scarring alopecia,¹⁸⁷³ esophageal and anal strictures,¹⁸⁷⁴ choanal atresia,¹⁸⁷⁵ Chiari I malformation,¹⁸⁷⁶ and an increased incidence of malignancy, particularly related to the mucous membranes^{1871,1877,1878} and, less commonly, the skin.¹⁸⁷⁹ Bone marrow failure is the major cause of premature death.

Although found predominantly in Caucasian males, it has been reported in several races and occasionally in females.¹⁸⁸⁰ Most cases are inherited as a sex-linked recessive trait,¹⁸⁷¹ but kindreds with both autosomal dominant and autosomal recessive inheritance have been reported.^{1881,1882} The various types of dyskeratosis congenita are listed in Table 3.6. In all characterized cases of dyskeratosis congenita, the causative mutations are present in components of the telomerase complex. Chromosomes shorten during DNA replication, and it is the function of telomerase to add telomere repeats (a repeat comprises six nucleotides) to the ends of chromosomes.¹⁸⁸² The gene for X-linked recessive dyskeratosis congenita, *DKC1*, which encodes a 514-amino acid protein, dyskerin, is located at Xp28.¹⁸⁸³ The disease is predominantly caused by missense mutations in this gene.¹⁸⁸⁴ It is thought that dyskerin is a nucleolar protein that is responsible for some early steps in ribosomal-RNA processing.¹⁸⁸³ This defect appears to be associated with a more severe phenotype than the autosomal dominant form, which has heterozygous mutations in either *TERC* or *TERT*, the RNA and enzymatic components of telomerase, respectively.¹⁸⁸² The majority of documented cases of this form involve *TERC* mutations. The *TINF2* gene appears to be another candidate gene. Autosomal recessive dyskeratosis congenita is more enigmatic. A homozygous mutation in *NOPI0* (*NOLA3*) has been found in a consanguineous family. This mutation results in short telomeres and low *TERC* levels.¹⁸⁸²

The skin changes, which may resemble poikiloderma, usually develop on the face, neck, and upper trunk in childhood. It has been suggested that there may be pathogenetic features in common with graft-versus-host disease.¹⁸⁶⁵

Nevus anemicus-like changes have been described in a case of X-linked recessive dyskeratosis congenita.¹⁸⁸⁵ Treatment with anabolic steroid and hematopoietic growth factors can produce an

Table 3.6 Genetic variants of dyskeratosis congenita

OMIM	Inheritance	Gene defect	Gene product	Locus	Alternative name

Figure 3.38 Dyskeratosis congenita. There are hyperkeratosis, foci of epidermal atrophy, and pigment incontinence, particularly on the left side of the figure. This biopsy was obtained from an individual with the autosomal dominant, Scoggins type of the disease. (H&E)

improvement in hematopoietic function for some time,¹⁸⁸⁶ but eventually allogeneic stem cell transplantation is needed. Because of the pulmonary vascular complication, this procedure has not been particularly successful.¹⁸⁸² In the future, gene therapy with the introduction of the wild-type form of the defective gene into stem cells should correct downstream defects in this disease.¹⁸⁸²

Histopathology

Usually, there are mild hyperkeratosis, epidermal atrophy, prominent telangiectasia of superficial vessels, and numerous melanophages in the papillary dermis (Fig. 3.38). Less constant features include mild basal vacuolar change, fibrosis of the upper dermis, and a mild lymphocytic infiltrate beneath the epidermis.¹⁸⁸⁵ Civatte bodies have not been recorded.

Differential diagnosis

A resemblance of some examples of dyskeratosis congenita to graft-versus-host disease, both clinically and microscopically, has been mentioned in several publications.^{1887,1888} Generally, vacuolated changes of the basilar layer are more pronounced in graft-versus-host disease than in dyskeratosis congenita lesions, but there can be sufficient overlap that clinical and genetic evaluation may be necessary to permit distinction between these two disorders.

POIKILODERMA OF CIVATTE

Poikiloderma of Civatte is a common dermatosis, particularly in Greece and other areas of Europe; it can produce cosmetic disfigurement.¹⁸⁸⁹ It is a neglected and controversial entity that has received little attention in other areas of the world. It most often affects fair-skinned individuals in their fourth to seventh decades. It is characterized by red to brownish, reticular patches with irregular borders and symmetrical distribution. It may involve the 'V-area' and sides of the neck, the upper chest, and parts of the face.¹⁸⁹⁰ Erythematotelangiectatic and pigmented types occur. The etiology is unknown, but it is considered to be the cumulative effect of sun exposure exacerbated by the application of fragrances to the neck in combination with genetic predisposition and lighter skin phenotypes.^{1889,1891}

Sun protection and the avoidance of documented allergens should be practiced.¹⁸⁸⁹ Several patients who have been treated with pulsed dye laser have developed severe depigmentation.¹⁸⁹¹ Depigmenting

Figure 3.39 Pityriasis lichenoides (acute form). The dermoepidermal interface is obscured by the inflammatory cell infiltrate. (H&E)

agents can be used as adjuvants in the pigmented variant of the disease.¹⁸⁹⁰

Histopathology

There is variable telangiectasia and melanin incontinence. Mild epidermal atrophy is sometimes present, particularly in older lesions. Some solar elastosis is invariably seen. Mild vacuolar change is sometimes present. There are sparse perivascular lymphocytes. Intense pulsed light therapy has been used successfully to treat some cases of poikiloderma of Civatte; histopathologic studies before and after treatment show greater homogeneity of melanin distribution, increased collagen density, and an increase of nonfragmented elastic fibers following application of this mode of therapy.¹⁸⁹²

OTHER LICHENOID (INTERFACE) DISEASES

In addition to the dermatoses discussed previously, a number of other important diseases may show features of the lichenoid reaction pattern. They are discussed more fully in other chapters, but they are also included here for completeness. Only the salient histological features are mentioned.

LICHEN SCLEROSUS ET ATROPHICUS

In early lesions, the inflammatory infiltrate is quite heavy with band-like qualities mimicking lichen planus. Both vacuolar change and apoptotic basal keratinocytes are present. The infiltrate is eventually pushed downwards by an expanding zone of edema and sclerosis (see p. 361).

PITYRIASIS LICHENOIDES

In the acute form of pityriasis lichenoides, pityriasis lichenoides et varioliformis acuta (PLEVA), there is a heavy lymphocytic infiltrate that obscures the dermoepidermal interface in much the same way as it does in erythema multiforme and fixed drug eruption (Fig. 3.39). This may be associated with focal epidermal cell death and overlying parakeratosis or confluent epidermal necrosis.¹⁸⁹³ The dermal infiltrate varies from a mild lymphocytic vasculitis to a heavy infiltrate that also extends between the vessels and is accompanied by variable

hemorrhage. The dermal infiltrate is often wedge-shaped in distribution, with the apex toward the deep dermis. PLEVA is considered further with the lymphocytic vasculitides in Chapter 8.

PERSISTENT VIRAL REACTIONS

There is increasing recognition that viral and putative viral infections may be followed by a spectrum of cutaneous reactions that often includes the lichenoid tissue reaction. Examples include lichenoid lymphocytic vasculitis (see p. 256) that occurs with persistent herpes simplex infection, the Gianotti–Crosti syndrome (see p. 128),¹⁸⁹⁴ and reactions resembling mild pityriasis lichenoides. A chronic lichenoid dermatosis has been reported in several patients as an unusual manifestation of both herpes simplex and varicella–zoster infection. There was a lichenoid reaction but no cytolytic host response.¹⁸⁹⁵ Late stages of pityriasis rosea (included here as a putative viral infection) often show prominent epidermal cell death. Basal vacuolar change is usually present in these various reactions.

Asymmetric periflexural exanthem of childhood, also known as unilateral laterothoracic exanthem, is a putative viral disease with pruritic, unilateral macules and papules. It has a distinctive perisudoral CD8⁺ infiltrate at the interface. Lymphocytes have also been found around the eccrine coils. Apoptotic basal keratinocytes are also present.^{1896,1897}

PERNIOSIS

In some cases of perniosis, a mild lichenoid reaction is present. It is mostly focal. The changes are more prominent in cases of chilblain lupus (lupus pernio). There is usually no parakeratosis, unlike pityriasis lichenoides, which also combines a lichenoid and vasculitic tissue reaction. In perniosis, there is usually a thick layer of orthokeratin reflecting the acral site.

PARANEOPLASTIC PEMPHIGUS

Paraneoplastic pemphigus (see p. 167) resembles erythema multiforme, with a lichenoid tissue reaction and dyskeratotic cells at different levels of the epidermis. Usually, foci of suprabasal acantholysis and clefting are also present. Subepidermal clefting has also been reported. A lichenoid variant of paraneoplastic pemphigus has been described without detectable autoantibodies.¹⁸⁹⁸

LICHENOID PURPURA

Some lesions of pigmented purpuric dermatosis may show lichenoid as well as purpuric and chronic vasculitic features (see p. 264). The presence of purpura and of hemosiderin are important clues to the diagnosis.

LICHENOID CONTACT DERMATITIS

A lichenoid contact dermatitis has been seen after contact with rubber and certain clothing dyes and also following contact with chemicals used in the wine industry. In two personally studied cases, there was a patchy, band-like dermal infiltrate of lymphocytes with a few eosinophils and very mild basal spongiosis.

STILL'S DISEASE (ADULT ONSET)

A unique pattern of dyskeratosis has been reported in cases of adult-onset Still's disease (fever, polyarthralgia, lymphadenopathy, and evanescent rash).^{1899,1900} There are multiple dyskeratotic cells, singly or in

aggregates, mainly located in the upper epidermis, including the stratum corneum.¹⁸⁹⁹ There are no associated lymphocytes. The presence of neutrophils in the dermal infiltrate is another characteristic feature.¹⁸⁹⁹

LATE SECONDARY SYPHILIS

Some lesions of late secondary syphilis show a lichenoid reaction pattern (see p. 675). There is usually extension of the inflammatory infiltrate into the mid and deep dermis. Plasma cells are usually present in the infiltrate.

POROKERATOSIS

In lesions of porokeratosis, particularly the disseminated superficial actinic form, a lichenoid tissue reaction associated with a heavy superficial lymphocytic infiltrate can occur. A careful search will reveal the diagnostic cornoid lamella at the periphery of the infiltrate. The lichenoid infiltrate may be directed against the abnormal epidermal clones that emerge in this condition. Porokeratosis is considered in detail in Chapter 9.

DRUG ERUPTIONS

The lichenoid reaction pattern is a prominent feature in lichenoid and fixed drug eruptions. In many other drug-induced cutaneous reactions, a very occasional Civatte body (apoptotic keratinocyte) may be seen in the basal layer or at a higher level within the epidermis. There may be an associated exocytosis of a few lymphocytes. Apoptotic cells are a valuable clue to the drug etiology of an otherwise nonspecific spongiotic tissue reaction (see p. 128). These cells are usually easier to find in morbilliform drug eruptions.

PHOTOTOXIC DERMATITIS

In a phototoxic dermatitis, there are scattered apoptotic keratinocytes (dyskeratotic cells and sunburn cells) at all levels of the epidermis. In severe cases, confluent necrosis may be present. There is some telangiectasia of superficial dermal vessels but very little dermal inflammation.

PRURIGO PIGMENTOSA

A patchy lichenoid reaction with associated melanin incontinence is seen in this uncommon condition (see p. 339).

ERYTHRODERMA

A lichenoid reaction is present in some patients with erythroderma (see p. 591). Many of these cases may be drug induced.

MYCOSIS FUNGOIDES

A subset of patients with mycosis fungoides have lichenoid changes on biopsy. One study found that lichenoid changes tend to be associated with intense pruritus and may connote a poor prognosis.¹⁹⁰¹ The presence of basal epidermotropism, nuclear atypia in the lymphocytes, and the presence of eosinophils and sometimes plasma cells in the dermal infiltrate are helpful in identifying the underlying mycosis fungoides.¹⁹⁰¹

REGRESSING WARTS AND TUMORS

The regression of viral warts, particularly plane warts, is associated with a lichenoid reaction pattern and exocytosis of cells into the epidermis. Keratinocytes in the stratum malpighii, presumably expressing viral antigen, are attacked by lymphocytes, resulting in death of the keratinocytes by apoptosis. Sometimes two or more lymphocytes 'surround' a keratinocyte, similar to the 'satellite cell necrosis' (lymphocyte-associated apoptosis) of graft-versus-host disease.

A lichenoid reaction pattern can be associated with a variety of epidermal tumors, where it appears to represent the attempted immunological regression of those lesions. This may be seen in seborrheic keratoses (the so-called 'irritated' seborrheic keratosis), solar keratoses (lichenoid solar keratoses), and intraepidermal carcinomas. The lichen planus-like keratosis represents a similar reaction in a solar lentigo and probably some other epithelial lesions.

A similar mechanism is involved in the partial regression of basal and squamous cell carcinomas and other cutaneous tumors. However, these circumstances do not conform to the definition of the lichenoid reaction pattern, namely basal epidermal cell damage. Accordingly, they are not considered further in this section.

LICHEN AMYLOIDOSUS

In lichen amyloidosis, there is an accumulation of filamentous material in basal cells, with their eventual death. The filamentous material is extruded into the dermis in a manner similar to the formation of colloid bodies. The basal cells possibly die by apoptosis, but the accumulation of the filamentous material obscures this basic process (see p. 435).

VITILIGO

In active lesions of vitiligo, careful search will often reveal an occasional lymphocyte in contact with a melanocyte. The destruction of melanocytes by lymphocyte-mediated apoptosis would explain the features of vitiligo (see p. 323).

LICHENOID TATTOO REACTION

A lichenoid reaction, localized to the areas of red ink deposits, is a rare complication in a tattoo.

MISCELLANEOUS CONDITIONS

A lichenoid reaction may be seen in several other circumstances in which it is not usually a feature. Examples include candidiasis of the lip and pityriasis rubra pilaris. A pinpoint lichenoid reaction may also be seen in polymorphic light eruption. A mild lichenoid reaction with pigment incontinence was seen in one case of immunosseous dysplasia (OMIM 242900), which is caused by mutations in the *SMARCA1* gene.¹⁹⁰²

Figure 3.40 Lichenoid and granulomatous dermatitis. This image shows a cohesive arrangement of macrophages, many of them epithelioid in type, in a band-like distribution within the papillary dermis.

LICHENOID AND GRANULOMATOUS DERMATITIS

Magro and Crowson reported 40 cases of lichenoid inflammation with a granulomatous component.³⁷ A drug was implicated in 14 cases. More than one-third of these patients with drug-related eruptions had other medical illnesses associated with cutaneous granulomatous inflammation, such as rheumatoid arthritis, Crohn's disease, and hepatitis C.³⁷ A microbial trigger was implicated in 12 patients in the context of infective 'id' reactions to viral, fungal or bacterial diseases. Hepatobiliary disease, rheumatoid arthritis, and cutaneous T-cell lymphoma were other associations.³⁷ The drugs included antibiotics, lipid-lowering agents, ACE inhibitors, and anti-inflammatory drugs.³⁷

A lichenoid and granulomatous reaction has since been reported in a patient presenting with erythroderma resulting from erythropoietin.¹⁹⁰³ The author has seen a similar pattern produced by allopurinol.

Breza and Magro have also reported three cases of this combined pattern in three patients with atypical (nontuberculous) mycobacterial infection.¹⁹⁰⁴ Five microscopic patterns have been described by Magro and Crowson, based mainly on the distribution of macrophages within the dermis; these include loose, cohesive, and diffuse interstitial arrangements, as scattered giant cells, and in the form of granulomatous vasculitis (**Fig. 3.40**).³⁷

Pityriasis rubra pilaris	93	Norwegian scabies	99	Secondary syphilis	101
Parapsoriasis	95				

INTRODUCTION

The psoriasiform reaction pattern is defined morphologically as the presence of epidermal hyperplasia with elongation of the rete ridges in a regular manner. This definition encompasses a heterogeneous group of dermatological conditions. This morphological concept is much broader than the pathogenetic one, outlined by Pinkus and Mehregan.¹ They considered the principal features of the psoriasiform tissue reaction to be the formation of a suprapapillary exudate with parakeratosis, secondary to the intermittent release of serum and leukocytes from dilated vessels in the papillary dermis (the so-called 'squirting papilla').

The increased mitotic activity of the epidermis that results in the elongated rete ridges and the psoriasiform epidermal hyperplasia is presumed to be secondary to the release of various mediators from the dilated vessels in the papillary dermis in psoriasis. These aspects are discussed in further detail later. The epidermal hyperplasia in lichen simplex chronicus may be related to chronic rubbing and irritation, whereas in Bowen's disease there is increased mitotic activity of the component cells. In many of the conditions listed, the exact pathogenesis of the psoriasiform hyperplasia remains to be elucidated.

Psoriasis is the prototype of the psoriasiform reaction pattern, but note that early lesions of psoriasis and pustular psoriasis show no epidermal hyperplasia, although there is evidence of a 'squirting papilla' in the form of dilated vessels and exocytosis of inflammatory cells with neutrophils collecting in the overlying parakeratotic scale.

The major psoriasiform dermatoses – psoriasis, psoriasiform keratosis, pustular psoriasis, Reiter's syndrome, pityriasis rubra pilaris, parapsoriasis and its variants, and lichen simplex chronicus – are considered first.² The other dermatoses listed as causes of the psoriasiform reaction pattern have been discussed in detail in other chapters. They are included again here for completeness, with a brief outline of the features that distinguish them from the other psoriasiform dermatoses.

MAJOR PSORIASIFORM DERMATOSES

This group of dermatoses is characterized, as a rule, by regular epidermal hyperplasia, although in the early stages such features are usually absent. Psoriasis, which is the prototype for this tissue reaction, is considered first.

PSORIASIS

Psoriasis (psoriasis vulgaris) is a chronic, relapsing, papulosquamous dermatitis characterized by abnormal hyperproliferation of the epidermis.² It affects approximately 2% of the population and involves all racial groups, although it is uncommon in Africans,³ South American Indians,^{4–6} and other indigenous people (Inuit, Aborigines, and Ami).⁷ Its incidence rate in a study from the United Kingdom was 14 per 10,000 person-years,⁸ whereas a prevalence rate of just over 1% was recorded in a Spanish study.⁹ Its incidence is high in Norway.¹⁰

Psoriasis typically consists of well-circumscribed erythematous patches with a silvery white scale (plaque form). Characteristic bleeding points develop when the scale is removed.¹¹ This has been called Auspitz's sign, although it appears that he has been wrongly credited with this observation.¹² Pruritus is sometimes present.^{13,14} There is a predilection for the extensor surfaces of the extremities, including the elbows and knees, and also the sacral region, scalp,¹⁵ and nails.^{16,17} There is a broad spectrum of nail dystrophies associated with psoriasis, ranging from the common pitting, distal onycholysis, and loosening of

the nail plate to the less frequent discoloration and splinter hemorrhages seen in the nail bed.¹⁸ Linear nail pitting and splinter hemorrhages are more common in psoriasis than in psoriatic arthritis.¹⁹ Subungual hyperkeratosis may also develop.²⁰ Involvement of the palms and/or soles occurs in less than 20% of patients with psoriasis.²¹ A scarring alopecia is rare.^{22,23} The lips are not commonly involved,^{24–27} and oral lesions in the form of whitish areas on the mucosa are quite rare,²⁸ but fissured tongue and geographic tongue are not infrequent and can be seen in both plaque type and pustular psoriasis.^{29,30} Centropalmar involvement is a marker of severe disease.^{31,32} Penile lesions are more common in uncircumcised men.³³ When psoriasis involves the anogenital region of females, vulval scarring may ensue.³⁴ Lesions may develop at sites of trauma and in peristomal skin.³⁵

In 5% or more of psoriatics, a seronegative polyarthritis develops.^{4,36} Controversy exists as to whether they represent two related but different disease processes.³⁷ A review highlighted their overlapping etiology and pathogenesis.³⁷ Achilles tendinitis is frequent in patients with psoriatic arthritis.³⁸ Psoriatic onychopachydermo-periostitis (POPP) is a rare subset of psoriatic arthritis.³⁹ Bilateral upper limb lymphedema has been reported in a patient with arthritis.⁴⁰ Psoriasis has also been reported in association with obesity,⁴¹ vitiligo,^{42–45} gout,⁴⁶ diabetes,^{47–49} ankylosing spondylitis, inflammatory linear verrucous epidermal nevus (ILVEN),⁵⁰ HIV infection,⁵¹ benign migratory glossitis (geographic tongue),^{52,53} minor hair shaft abnormalities,⁵⁴ gliadin antibodies,^{55–57} and inflammatory bowel disease, particularly Crohn's disease.^{36,58,59} Its association with bullous pemphigoid and other bullous diseases,^{60–63} perforating folliculitis,⁶⁴ lupus erythematosus,^{65,66} Kawasaki disease,^{67–69} hyper-IgE syndrome,⁷⁰ prolactinoma,⁷¹ Vogt-Koyanagi-Harada syndrome,⁷² insulinoma,⁷³ CD4⁺ lymphocytopenia,⁷⁴ Laurence-Moon-Biedl syndrome,⁷⁵ epidermal nevi, multiple exostoses, and surgical scars⁷⁶ is probably a chance occurrence. Some studies have shown an elevated risk of malignancy in patients with psoriasis, especially among younger and male patients.⁷⁷ A statistically significant relationship has been found between psoriasis and colon cancer.⁷⁸ There is a slight increase in the incidence of lymphoma and carcinoma of the larynx in patients with psoriasis, which is unrelated to mode of treatment.^{79–81} Patients with psoriasis are more likely to have one or more autoimmune diseases, the strongest association being with rheumatoid arthritis.⁸² Psoriasiform eruptions may be a paraneoplastic phenomenon.⁸³ Heart disease appears to be increased in patients with psoriasis, as a consequence of increased atherosclerosis.^{48,84–87} This may be a consequence of significantly decreased levels of high-density lipoproteins.^{88,89} Serum leptin levels are increased in patients with psoriasis.⁹⁰ Patients show signs of insulin resistance.⁹¹ Severe but not mild psoriasis is associated with an increased risk of death.⁹²

The mean age of onset of psoriasis is approximately 25 years, although it also develops sporadically in older persons, in whom it tends to have a milder course.^{93–96} Childhood cases are not uncommon,^{97–100} particularly in Scandinavia, where the disease commences in childhood in a high proportion of cases.¹⁰¹ Plaque psoriasis is the most common type in childhood.¹⁰² In those younger than 2 years of age, a psoriatic diaper rash with dissemination is the most common type.¹⁰² Congenital onset is a rare occurrence.¹⁰³ A family history of psoriasis and an association with HLA-Cw6 are often present in those with early onset.^{100,104,105}

Facial involvement, nail involvement, and Koebner reactions are more common in early onset psoriasis.⁹⁶ Psoriasis usually runs a chronic course, although spontaneous or treatment-induced remissions may occur. Its spontaneous clearance during the course of Kikuchi's disease has been reported.¹⁰⁶ It can have a significant effect on the quality of life in those persons with the disease.^{107,108} Patients with palmoplantar psoriasis have more disability and discomfort than patients with other forms of psoriasis.¹⁰⁹ In order to assess the effects of treatment on psoriasis, various indices of severity and area of involvement have been devised.^{110,111}

Clinical variants

Several clinical variants of psoriasis have been recognized. *Guttate psoriasis* consists of 1- to 5-mm erythematous papules, which eventually develop a fine scale. It may be preceded by a streptococcal pharyngitis.^{112–115} Evidence of a preceding streptococcal infection is found in approximately two-thirds of cases of guttate psoriasis.¹⁵ T lymphocytes specific for group A streptococcal antigens have been isolated from lesions of guttate psoriasis.¹¹⁶ There is a predilection for the trunk, and it is more common in children.¹¹⁷ Clearing may occur spontaneously in weeks or months.¹⁵ Psoriasis begins as the guttate form in 15% or more of cases.¹⁰⁵ It appears that a subset of patients with guttate psoriasis undergo complete or long-term remission, whereas another group has a chronic course, without remission and with progression to chronic plaque psoriasis. Among the former, there is an earlier age of onset with high ASO titers, whereas the latter tend to have a somewhat later age of onset and a family history of psoriasis.¹¹⁸ *Erythrodermic psoriasis* develops in approximately 2% of psoriatics, and it accounts for 20% or more of erythrodermas.^{119–122} It is a severe form involving more than 90% of the skin with a high morbidity and an unpredictable course.¹⁵ A verrucous form of erythrodermic psoriasis has been described.¹²³ Erythrodermic psoriasis may be precipitated by administration of systemic steroids, by the excess use of topical steroids, by radiologic contrast media,¹²⁴ or by a preceding illness; it may develop as a complication of phototherapy.¹¹⁹ Peripheral blood eosinophilia may be present in this form.¹²⁵ *Sebopsoriasis* consists of yellowish-red, less well-margined lesions, with variable degrees of scaling, often distributed in seborrheic regions of the body.¹²⁶ Rare clinical variants include a nevroid form,^{127,128} sometimes along the lines of Blaschko,¹²⁹ photosensitive psoriasis,¹³⁰ inverse (flexural) psoriasis,¹³¹ follicular psoriasis,^{132,133} psoriasis spinulosa,^{117,134} psoriasis bullosa acquisita,¹³⁵ congenital erythrodermic psoriasis,¹³⁶ interdigital psoriasis,¹³⁷ rupioid psoriasis,¹³⁸ annular plaque-type psoriasis,¹³⁹ annular verrucous psoriasis,¹⁴⁰ verrucous (hypertrophic) psoriasis,¹⁴¹ erythema gyratum repens-like psoriasis,¹⁴² erythema annulare centrifugum-type psoriasis,¹⁴³ and linear psoriasis,^{65,144–147} although the occurrence of a linear form of psoriasis is not accepted by some authorities. Linear psoriasis can be superimposed upon other forms of the disease and may reflect a clone of cells harboring a postzygotic mutation.^{148,149} Psoriasiform napkin dermatitis may also be a variant of psoriasis.^{102,150} Pustular psoriasis is regarded as a discrete entity. Different forms of the disease may alter their morphology and become a different clinical type. This phenotype switching may be a consequence of alterations in interleukin pathways.¹⁵¹

Cases reported as *psoriasiform acral dermatitis* are now thought to represent a variant of psoriasis in children and not a discrete entity. This variant is characterized by cutaneous involvement of the digits without nail dystrophy.¹⁵²

Genetics of psoriasis

There is a genetic proclivity to psoriasis, but no precise mode of inheritance is clear.^{93,153–157} The pattern is polygenetic¹⁵⁸ rather than single-gene inheritance. A recessive mode of inheritance has been suggested in Swedish patients.¹⁵⁹ Concordance in monozygotic twins varies from 35% to 70% or more.^{93,160} It is 15–30% in dizygotic twins.¹⁶¹ These statistics suggest that non-shared environmental influences also play a role.¹⁶²

Since 1994, many genetic loci (mainly on chromosomes 17q, 4q, 2p, 1q, and 6p) comprising at least nine genes have been under investigation.^{7,163–166} At least 19 different putative loci for genetic susceptibility to psoriasis have been reported.^{10,167} Recent studies suggest that there is a major susceptibility region for psoriasis on chromosome 6p21.3, near to HLA-C.^{168–174} It has been estimated that the proportion of genetic susceptibility attributable to this gene (*PSORS1C3*) is approximately 30%.¹⁷⁵ Attempts to link this gene to the *CDSN* gene

(corneodesmosin), also near to HLA-C, were initially unsuccessful.¹⁵⁹ Both genes as well as the nearby *HCR* gene are now regarded as important psoriasis susceptibility genes in Chinese patients with psoriasis,^{176,177} although this has been questioned.¹⁶¹ The *CDSN* gene is associated with psoriasis vulgaris in Caucasian but not in Japanese populations.¹⁷⁸ However, *PSORS1* shows epistasis with genes at other locations, such as on 1p.¹⁷⁹ *PSORS1* contains several genes, some of which have an association with psoriasis.¹⁸⁰ Another study of psoriasis in Chinese patients suggested that the *MICA* gene, another HLA-related gene on chromosome 6p21.3, may be a candidate gene.¹⁸¹ The *ACE* gene variants may confer susceptibility in some populations.^{182,183} The leptin gene did not appear to be involved in a Turkish population.¹⁸⁴ Promoter region polymorphisms in the tumor necrosis factor- α (*TNF- α*) gene have been associated with early onset psoriasis in a Polish population but not in Japanese, Chinese, or Korean people.^{185,186} In contrast, *IL-12B* gene polymorphisms, another cytokine gene, did confer a risk for psoriasis vulgaris in several different populations.^{186,187} Polymorphisms in the *PTPN22* region are associated with psoriasis of early onset.¹⁸⁸ Other proinflammatory genes have also been implicated.^{189–191} Recent studies have resulted in an increase in the number of candidate genes in psoriasis and psoriatic arthritis cohorts, which can be grouped into signaling networks affecting skin barrier function (*LCE3*, *DEFB4*, and *GJB2*), innate immune responses involving nuclear factor- κ B (*NF- κ B*) and interferon signaling (*TNFAIP3*, *TNIP1*, *NFKBIA*, *REL*, *FBXL19*, *TYK2*, and *NOS2*), and adaptive immune responses connected with CD8⁺ T cells and IL-23/IL-17-mediated lymphocyte signaling (*HLA-C*, *IL12B*, *IL23R*, *IL23A*, *TRAF3IP2*, and *ERAP1*).¹⁹²

Psoriasis is associated with HLA-Cw6, B13 and B17 on serology,^{93,193–196} and specifically with HLA-Cw*0602, HLA-DQA1*0104, and HLA-DRB1*0701 by polymerase chain reaction.^{171,197–201} An early study showed that all patients with guttate psoriasis carried the HLA-C allele compared with 20% of the control population.²⁰² This has not been confirmed by a subsequent study that concluded that the role of this allele in psoriasis has yet to be determined.²⁰³ It has been suggested that *PSORS1* may indeed be the HLA-CW*06 allele encoding the HLA-CW6 molecule.⁷

MicroRNAs are implicated in the pathogenesis of psoriasis and also atopic eczema. Their effects may be mediated through a number of secondary pathways, including the *TNF- α* pathway.²⁰⁴

Trigger factors

Specific factors may trigger the onset or exacerbation of psoriasis. Trauma, infections,^{205,206} and drugs are accepted triggers, whereas the roles of climate, hormonal factors, cigarette smoking,^{8,207,208} alcohol,²⁰⁸ mesotherapy,²⁰⁹ internal malignancy,^{210,211} and stress²¹² are sometimes disputed.⁹³ Psoriasis may actually improve during pregnancy.^{213,214} It is often worse in the postpartum period.^{214,215} The development of lesions in response to trauma (Koebner reaction) is present in approximately one-third of cases.^{216,217} A link has been made between psoriasis and human papillomaviruses specifically associated with epidermodysplasia verruciformis, particularly the oncogenic HPV-5.²¹⁸ The prevalence of HPV in hairs plucked from patients with psoriasis is increased in patients treated with PUVA.²¹⁹ However, one study did not find a specific causal role for HPV-5 or HPV-36 in the pathogenesis of psoriasis.²²⁰ The role of *Malassezia* is more controversial. The improvement of scalp psoriasis treated with antifungal agents has suggested a role for *Malassezia*. *Malassezia restricta* is the predominant species in psoriatic scale. *Malassezia globosa* is also increased, but much less so.²²¹ Cell wall-deficient bacterial infection may be a triggering factor through its effect on T-cell activation.²²² Infection may precipitate guttate psoriasis.^{112,223} Various drugs may precipitate or exacerbate psoriasis,^{224,225} particularly lithium;^{226–228} other drugs include ecstasy,²²⁹ quinidine,²³⁰ clonidine, iodine, carbamazepine,^{231,232}

Table 4.1 Drugs precipitating/exacerbating psoriasis

ACE inhibitors	Infliximab
Adalimumab	Interferon- α
Ampicillin	Interleukin-2
Anakinra	Iodine
Antimalarials	Isotretinoin
β -Blockers	Lithium
Calcium channel blockers	NSAIDs
Carbamazepine	Olanzapine
Celecoxib	Propafenone
Cimetidine	Quinidine
Clonidine	Rofecoxib
Ecstasy	Terbinafine
Fluorescein sodium	Terfenadine
Glibenclamide	Tetracyclines
Icodextrin	Thalidomide
Imiquimod	Urapidil
Indomethacin	Voriconazole

olanzapine,²³³ thalidomide,²³⁴ terbinafine,^{235,236} indomethacin,²³⁰ rofecoxib,²³⁷ celecoxib,²³⁷ various β -blocker drugs,^{238,239} calcium channel blockers,²⁴⁰ terfenadine,²⁴¹ urapidil (an α_1 -adrenergic blocker),²⁴² isotretinoin, interferon- α (IFN- α),^{207,243} interleukin-2 (IL-2),²⁴⁴ the IL-1 receptor antagonist anakinra,²⁴⁵ the TNF- α agonists adalimumab and infliximab,^{246–251} imiquimod,^{252–255} antimalarials and, rarely, the nonsteroidal anti-inflammatory drugs and the angiotensin-converting enzyme (ACE) inhibitors.²⁵⁶ However, a population-based case-control study found no association between the use of β -blockers and psoriasis.²⁵⁷ Drugs that precipitate/exacerbate psoriasis are listed in **Table 4.1**. It has been suggested that the eruptions produced by TNF- α agonists may be a ‘new model of adverse drug reaction’ rather than true psoriasis because the histology shows lichenoid and spongiotic features.²⁵⁸ The eruption triggered by efalizumab, a human anti-CD11a monoclonal antibody used in the treatment of psoriasis, consists of new papular lesions that arise in previously unaffected areas.²⁵⁹ They usually do not necessitate termination of efalizumab therapy and may optionally be treated with corticosteroids.²⁵⁹ A psoriasiform eruption, as opposed to true psoriasis, has been reported as a complication of several β -blocker drugs,²⁶⁰ and the related propafenone,²⁶¹ with fluorescein sodium used in angiography,²⁶² with the oral hypoglycemic agent glibenclamide,²⁶³ with icodextrin,²⁶⁴ and with terbinafine (discussed previously).²⁶⁵ The reactions caused by some of the β -blocker drugs have a lichenoid histology despite their clinical appearance. Psoriasis has also followed the use of stem cell transplantation.^{266,267}

Pathogenesis of psoriasis

Psoriasis is a complex disease in which numerous abnormal findings have been reported.^{157,268} Despite this, the primary (initiating) alteration is unknown, but it appears that the molecular phenotype necessary for the clinical expression of psoriasis is present in all keratinocytes and includes a capacity for hyperproliferation and altered differentiation. Control of the expression of this phenotype involves the keratinocytes as well as cells of the immune system and various cytokines.^{269–271} Many of the changes in these elements may be epiphenomena or secondary and tertiary events in the pathogenetic cascade. As mentioned previously, the primary alteration is not known, although it may involve the signal-transducing system of epidermal keratinocytes or the

transcription regulatory elements associated with one or more cytokines.^{272–274} Stimulation of the immune system by superantigens has also been put forward as a primary event (see later). It is possible that different etiologies may initiate psoriasis in the genetically susceptible individual. Various aspects of the pathogenesis of psoriasis, particularly the immunopathogenesis, have been reviewed.^{180,275,276}

Because the earliest detectable morphological change in psoriasis involves blood vessels in the papillary dermis, some research has focused on their role in the pathogenetic cascade.^{277–279} Vascular changes in psoriasis include dilatation and tortuosity of vessels in the papillary dermis, as well as angiogenesis (neovascularization)²⁸⁰ and the formation of high endothelial venules, which are specialized postcapillary venules lined by tall columnar or cuboidal endothelial cells. These factors are important in expanding the size of the microcirculation that may, in turn, facilitate the trafficking of T lymphocytes, of the Th1 subclass, into the skin,²⁸¹ thus maintaining the psoriatic plaque.²⁸² Blood flow is increased in these plaques.²⁸³ The high endothelial venules play an important role in the cutaneous recruitment of circulating lymphocytes.²⁸⁴ Microvascular hyperpermeability is another feature of severe psoriasis. This appears to be mediated by circulating vascular endothelial growth factor (VEGF).²⁸⁵ Angiogenesis is stimulated by factors such as IL-8 and transforming growth factor- α (TGF- α).^{277,286} The presence of angiogenesis in psoriasis has been challenged. Using three-dimensional reconstructions, it has been suggested that downgrowths of the rete ridges include the vessels of the horizontal plexus, giving the appearance of intrapapillary capillaries.²⁸⁷ This study has not been confirmed. In short, it appears that dermal capillary changes alone are unlikely to be causal in psoriasis.^{279,282}

Recruitment of lymphocytes to the papillary dermis is an important factor.²⁸⁸ This is aided by various chemoattractants such as platelet-activating factor and leukotriene B₄.²⁸⁹ Some of these lymphocytes are already activated before entering the skin, while still circulating in the bloodstream.²⁹⁰ The lymphocytes bind to endothelial cells in venules in the papillary dermis as a consequence of the enhanced expression of various adhesion molecules by endothelial cells.²⁹¹ It appears that lymphocyte function-associated antigen type 1 (LFA-1), consisting of CD11a and CD18 subunits,²⁹² which acts as a ligand for intercellular adhesion molecule-1 (ICAM-1), and ICAM-1 itself play a major role in the adhesion of CD4⁺ T cells to endothelial cells.²⁹³ Furthermore, TNF- α may play an important role in induction of adhesion molecules on endothelial cells.²⁹³ Vascular adhesion protein-1 (VAP-1) is also overexpressed in psoriasis.²⁹⁴ Efalizumab, an anti-CD11a antibody, has been used to treat psoriasis (see later). Lymphocytes then diapedese transendothelially and pass through the vessel wall into the papillary dermis. Neutrophils will subsequently leave the vessels in a similar way and migrate into the stratum corneum.²⁹⁵ Chemotactic factors such as C5a anaphylatoxin are important in their recruitment.²⁹⁶

Whereas the importance of T lymphocytes in the pathogenesis of psoriasis is accepted,^{297–299} there has been some dispute regarding the relative importance of CD4⁺ and CD8⁺ lymphocytes.³⁰⁰ The T cells in lesional dermis are predominantly CD4⁺. Cells migrating into the epidermis are mostly CD8⁺.^{180,301,302} Which type produces keratinocyte proliferation by the release of mediators (cytokines) is still disputed.³⁰³ Both now appear to be involved, but CD8⁺ cells are particularly important.^{180,304–306} CD8⁺ cells in the epidermis express the V β T-cell receptor subgroups V β 3 and V β 13.1.³⁰⁷ Another study has shown an increase in the V β 2 receptor in skin-homing lymphocytes in psoriasis.³⁰⁸ In psoriasis, CD4⁺CD25⁺ regulatory T cells are functionally deficient in suppressing effector T-cell proliferation.³⁰⁹

Recent work has focused on a subset of $\gamma\delta$ T cells that reside in the dermis. These cells are a major source of IL-17 in skin following IL-23 stimulation (see the following discussion) and are believed to play a role in the pathogenesis of psoriasis.³¹⁰ As mentioned previously, leukocytes bind to endothelial cells in the papillary dermis, prior to their

passage from the vessels. This process is under the control of adhesion molecules, which can be classified into three distinct groups:

- 1. The immunoglobulin gene superfamily, which includes ICAM-1 (CD54) and ICAM-2 and VCAM-1 (vascular cell adhesion molecule-1)
- 2. Integrins³¹¹
- 3. Selectins (the most important of which is E-selectin).

One or more of these adhesion molecules lead to the selective adhesion of CD4, CD45RO helper T cells.²⁸⁹ Other categories of adhesion regulators, such as the proline-directed serine/threonine kinases, of which CDK5 is a member, exist. They appear to influence cadherins and integrins.³¹² The expression of CDK5 is reduced in psoriasis.³¹² Various cytokines appear to induce the enhanced expression of these adhesion molecules in psoriasis; they include IL-1, IL-2, TNF- α , IFN- γ , and IL-4.^{288,313} On the other hand, ultraviolet-B radiation reduces the adhesive interactions and expression of adhesion molecules, possibly explaining its mode of action in the treatment of psoriasis.³¹⁴ Serum levels of soluble E-selectin correlate with the extent of psoriatic lesions.³¹⁵

There is a complex interplay between the various cytokines found in the skin in psoriasis; some cytokines have more than one action. They are produced mostly by lymphocytes, although keratinocytes release at least two.^{270,316,317} Dendritic cells and macrophages also produce important cytokines, one of which is IL-12. IL-12 induces differentiation of naive CD4 T lymphocytes to T-helper 1 (Th1) cells, which are key effector cells in the pathogenesis of psoriasis as a consequence of their production of various cytokines such as IFN- γ and IL-2.^{318,319} It also activates natural killer cells.³¹⁸ IL-23, which is closely related to IL-12 in structure, stimulates a subset of CD4⁺ lymphocytes to produce IL-17, which induces the production of further proinflammatory cytokines, predominantly by endothelial cells and macrophages.^{318,320} Therapy using an IL-12/IL-23 antibody is currently undergoing clinical trials (see later).³¹⁸ IL-18, a novel cytokine produced mainly by monocytes and macrophages but also synthesized by keratinocytes, plays an important role in the Th1 response by stimulating the production of IFN- γ and TNF. It is increased in the serum of patients with psoriasis.³²¹ In contrast, low levels of IL-10, an anti-inflammatory cytokine, have been found in psoriatic lesions.^{322,323} The many functions of these various cytokines include stimulation of keratinocytes,³²⁴ vascular changes (discussed previously), control of lymphocyte trafficking (discussed previously), and stimulation of neutrophil chemotaxis. Exacerbations of psoriasis are preceded by a rapid increase in neutrophil chemotaxis. IL-8 is a cytokine with possibly more chemotactic activity than the various complement factors.^{325–327} Another is psoriasin (S100A7), a protein belonging to the calcium-binding S100 family. It is a potent inflammatory mediator.³²⁸ Two other members of this family, S100A8 and S100A9, are increased in psoriasis and contribute to the hyperproliferation of psoriatic skin.³²⁹ The importance of the cytokines in the pathogenesis is shown by the downregulatory effects of cyclosporine (ciclosporin) on cytokines and cytokine receptors in the treatment of psoriasis.^{330,331} The role of the various cytokines in psoriasis has been reviewed.³³² They are summarized in Table 4.2.

The final pathway in the pathogenesis of psoriasis involves the stimulation of keratinocytes by factors such as TNF- α , IL-6, IL-8, TGF- α , IFN- γ , granulocyte/macrophage colony-stimulating factor, and the phospholipase C/protein kinase C signal transduction system (see later). IFN- γ , which plays an important role in the growth stimulation of keratinocyte stem cells in psoriasis, can be produced by mast cells as well as lymphocytes.³³³ TNF- α also has a major role. Its release from cells is under the influence of TNF- α -converting enzyme (TACE).³³⁴ The success of the various TNF- α neutralizing modalities in the treatment of psoriasis has led to a re-evaluation of the role of TNF- α in the pathogenesis of psoriasis. It seems likely that dysregulation of

Table 4.2 Cytokines in the pathogenetic cascade

Pathogenetic cascade	Cytokines involved
Endothelial activation and vascular changes	→ IL-1, IL-6, IL-8, TNF- α , TGF- α / β , IFN- γ , endothelin-1
↓	
Lymphocyte recruitment	→ IL-1, IL-8, MCP-1, TNF- α , psoriasin, CD11a/CD18 (LFA-1), ICAM-1
↓	
Keratinocyte–lymphocyte interactions	→ IL-1, IL-7, IL-8, TNF- α , IFN- γ , CD11a/CD18
↓	
Amplification of inflammatory mechanisms	→ IL-1, IL-2, IL-6, IL-8, IL-12, IL-17, IL-18, IL-23, TNF- α , IFN- γ , amphiregulin, MCP-1 (IL-10 is anti-inflammatory)
↓	
Keratinocyte proliferation	→ IL-1, IL-3, IL-6, IL-8, GM-CSF, IFN- γ , TGF- α , EGF, TNF- α , amphiregulin, endothelin-1, insulin growth factor, TGF- β receptors, GRO- α , phospholipase C/protein kinase C system, S100A8, S100A9, G-MCSF

After Bonifati and Ameglio (Int J Dermatol 1999; 38:241–251).

innate immunity, involving natural killer (NK) T cells, plays a role in the pathogenesis of psoriasis.³³⁵ This is supported by the finding of increased levels of perforin, the cytotoxic product of NK cells, in the epidermis of psoriatic plaques.³³⁶ Paradoxically, circulating NK cells are reduced in psoriasis.³³⁷ There is also an overexpression of the CXC chemokines, IL-8 and GRO/melanoma growth-stimulatory activity (GRO- α).³³⁸ They are potent activators of neutrophils and lymphocytes but also stimulate proliferation of keratinocytes.³³⁸ These factors produce an alteration in the turnover time for the epidermis: 3 or 4 days in psoriasis compared with the usual 13 days in normal skin.³³⁹ It has been estimated that there is a 12-fold increase in the number of basal and suprabasal keratinocytes in cell cycling.³⁴⁰ TGF- β , which is elevated in psoriasis, is predominantly synthesized in subcorneal keratinocytes.³⁴¹ It is a potent mitogen that can also stimulate angiogenesis. In contrast, TGF- β has an inhibitory effect on epithelial cell proliferation. Downregulation of its receptor in psoriatic epidermis has the effect of diminishing this inhibitory influence.³⁴² Amphiregulin, a cytokine that acts as an epidermal growth factor, is also increased in psoriatic keratinocytes.³⁴³ Transgenic mice engineered to overproduce amphiregulin develop a psoriasis-like phenotype, suggesting that a genetically transmitted alteration of amphiregulin synthesis may be a possible cause of the cascade of events in psoriasis.³¹⁹ There is increased activation of the Src family of tyrosine kinases (SFKs) in psoriasis.^{344,345} They are important regulators of epidermal growth and differentiation.³⁴⁴ The existence of an increased number of epidermal growth factor receptors (EGF-R), resulting from their persistence at all levels of the epidermis instead of just the basal layer, may be just as important.^{340,346} Antigen-presenting cells expressing the common heat shock protein receptor CD91 have been found juxtaposed to keratinocytes expressing HSP70, a ligand for CD91 in a mouse model of psoriasis.^{347,348} These activated antigen-presenting cells produce TNF- α in close proximity to these keratinocytes.³⁴⁷ T-cadherin, E-cadherin, P-cadherin, and protein kinase D expression all seem to play a part in the regulation of epidermal growth in psoriasis.^{349–351} Associated with this hyperproliferation of keratinocytes is a mild increase in apoptosis and a reduction in the number of Bcl-2-positive cells in the basal layer.^{352–355} Bcl-2 expression in lymphocytes is increased.³⁵⁶ Suppression of apoptosis also occurs in psoriasis.³⁵⁷ Survivin, a member of the

inhibitor of apoptosis protein (IAP) family, is increased in psoriasis. It appears to be regulated by the transcriptional factor NF- κ B.³⁵⁸ Some of the therapies for psoriasis act by their increase in apoptosis.³⁵⁹ A senescence switch involving p16 may prevent malignant transformation of this upregulated epidermis.³⁶⁰ Also, methylation of the p16^{INK4a} gene promoter is found in psoriatic epidermis.³⁶¹

As a consequence of the hyperproliferation of keratinocytes, there is enhanced expression of keratins K6, K16, and K17³⁶² and reduced amounts of the keratins indicative of differentiation (K1, K2, and K10). K16 is also expressed in nonlesional psoriatic skin and may serve as a marker of preclinical psoriasis.³⁶³ It has been found that altered peptide ligands derived from keratin 17 are capable of inhibiting proliferative responses of psoriatic T cells and keratinocyte proliferation *in vitro*.³⁶⁴ This opens up another therapeutic option in the treatment of psoriasis.³⁶⁴ There is a unique subpopulation of cells in psoriatic epidermis that coexpress K6 and K10.³⁶⁵ There is also increased nuclear β -catenin in suprabasal cells,³⁶⁶ alterations in cell-surface glycoconjugates,³⁶⁷ and variations in the epidermal differentiation complex – a cluster of genes on chromosome 1q21 that fulfill important functions in the terminal differentiation in the human epidermis.³⁶⁸ Tight junction components are also altered.³⁶⁹

The role of microbiological superantigens in the pathogenesis of psoriasis is gaining acceptance, although formal proof of a pathogenic role is still lacking.^{370–375} Superantigens are toxins of microbial origin that not only stimulate certain classes of T cells³⁷⁶ but also have the capability to interact directly (without prior processing) with MHC class II molecules: this leads to considerable T-cell activation and cytokine release.³⁷⁷ Streptococcal antigens can function as superantigens, and it is suggested that they may act as the initiating factor in some cases of guttate psoriasis, in part through superantigen-driven generation of V β -restricted CLA-positive skin-homing lymphocytes.^{378–380} One study has confirmed that prior pharyngeal infection is a risk factor for guttate psoriasis.³⁸¹ Peripheral blood lymphocytes from patients with psoriasis are generally hyporesponsive to streptococcal superantigens,³⁸² but there is a subpopulation of CD4⁺ cells that produces IFN- γ in response to this antigen.^{383,384} Superantigens produced by *Staphylococcus aureus* may also be triggering factors.^{385,386} *Malassezia furfur* is also capable of exacerbating psoriasis.³⁸⁷ Patients with psoriasis harbor human papillomavirus type 5 (HPV-5) in a significant number of cases.³⁸⁸ Antibodies to HPV-5, one of the types associated with epidermodysplasia verruciformis, appear to be generated in the epidermal repair process, but whether they contribute to a proliferation of keratinocytes in psoriasis is not known.³⁸⁸ The high prevalence of cytomegalovirus antigenemia in psoriasis is possibly related to reactivation of the virus by elevated levels of TNF- α .^{389,390} Endogenous retroviral sequences are expressed in psoriasis.³⁹¹ They are part of the normal human genome. Their possible role in the pathogenesis of psoriasis is currently being investigated.^{391,392} It has been suggested that a broad range of viral and bacterial stimuli may stimulate psoriasis, not by acting on T cells directly but by stimulating plasmacytoid dendritic cells (myeloid-derived cells) to produce large amounts of type I interferons (IFN- α/β).^{37,393} These disparate findings remain to be integrated into a unitarian theory of pathogenesis. It is possible that abnormalities in epidermal barrier function play a role in the pathogenesis of psoriasis, as is the case for a number of other disorders, such as Crohn's disease, that are considered 'barrier organ disorders'. A number of highly conserved genes – particularly nucleotide-binding domain, leucine-rich containing (NLR), or CATTERPILLER genes – are associated with barrier organs such as skin and contribute to the defense against microbial pathogens; the discovery of defects in this system in psoriasis could lead to novel therapeutic approaches.³⁹⁴ Other findings in psoriasis that may play some role in the pathogenetic cascade include the increased expression of heat shock proteins by keratinocytes,^{395–398} an increase in reactive oxygen species,³⁹⁹ excessive activation of a phospholipase C/

protein kinase C signal transduction system that stimulates keratinocyte proliferation,^{273,400,401} overexpression of serpin squamous cell carcinoma antigens in psoriatic skin,⁴⁰² and increased lysophosphatidyl choline activity in lesional skin. This substance is a lysophospholipid that is chemotactic for monocytes and stimulates the expression of certain adhesion molecules – VCAM-1 and ICAM-1.⁴⁰³ The finding of immunoreactants in the stratum corneum and the dermis is not thought to be of major pathogenetic significance.⁴⁰⁴ There is an upregulation of the gap junction protein connexin 26 between keratinocytes of psoriasis.⁴⁰⁵ There is also an overexpression of matrix metalloproteinases 2 (MMP-2) and 9 (MMP-9) and other related members of the ADAM family.^{406–408} Increased levels of kallikreins are also found in the stratum corneum and serum of patients with psoriasis.⁴⁰⁹ Telomerase activity is increased in peripheral blood mononuclear cells in psoriasis. The level correlates with disease severity.⁴¹⁰ There is also increased expression of the natural killer cell inhibitory receptor CD94/NKG2A and CD158b on circulating and lesional T cells in psoriasis, and this elevation correlates with disease severity.⁴¹¹ The significance of these findings is uncertain. Increased levels of elafin, also termed skin-derived anti-leukoprotease (SKALP), are found in subcorneal keratinocytes of psoriatic lesions.⁴¹² It is a potent elastase inhibitor that may protect the epidermis from the proteolytic activity of neutrophils.⁴¹² The epidermis is also protected against bacterial infections by the release of granulysin by lesional T cells and dendrocytes.⁴¹³ The exact role of neuropeptides (including substance P) remains to be clarified. They provide a possible explanation for the triggering action of stress in the exacerbation of psoriasis.⁴¹⁴ Increased serum cortisol levels are another possible mechanism by which stress influences psoriasis.⁴¹⁵ Serotonin levels are also increased in the lesions of psoriasis.⁴¹⁶

In concluding this section, it should not be forgotten that psoriasis is characterized by erythematous lesions. The erythematous nature of the lesions results from the dilatation and increase in vessels in the dermal papillae, which have a thin, overlying layer of epidermal keratinocytes. The clinical thickening of the lesions results from the psoriasiform epidermal hyperplasia brought about by increased mitotic activity in basal keratinocytes through the action of various cytokines with growth factor activity. The scale is composed of parakeratotic cells, resulting from increased transit time, and a focal admixture of neutrophils.⁴¹⁷ All of these features are possibly the consequence of an autoreactive inflammatory process mediated by T lymphocytes of the Th1 subclass.^{275,331} This cytokine profile may be the result of local factors and not determined by a specific genotype.⁴¹⁸

In assessing the treatment of psoriasis, the current benchmark is the Psoriasis Area and Severity Index (PASI). Reductions of 75% or more of this index are regarded as a suitable response to a particular therapy, and it has been suggested that a 50% reduction in the PASI is a meaningful response to any therapy.⁴¹⁹ Guttate psoriasis is managed with tar and UVB therapy (with questionable efficacy),⁴²⁰ dithranol and topical corticosteroids with or without UVB therapy, or calcipotriol (also a useful agent in other forms of psoriasis).⁴²⁰ Whereas antistreptococcal therapy is generally not effective in the management of guttate or plaque psoriasis,⁴²¹ tonsillectomy may be beneficial in select patients who have recurrent streptococcal infections.⁴²² Other therapies used in psoriasis include topical corticosteroids, most often used in tandem with other agents, calcineurin inhibitors,⁴²³ PUVA, narrowband UVB,⁴²⁴ and saltwater baths with UVB irradiation (balneophototherapy).⁴²⁵ Systemic medications that are used include the retinoids,⁴²⁶ methotrexate,⁴²⁷ cyclosporine,⁴²⁸ tacrolimus, mycophenolate mofetil, hydroxyurea, 6-thioguanine, and sulfasalazine. Among the currently used biologic agents are efalizumab (a CD11a blocker); TNF- α antagonists etanercept, infliximab, and adalimumab;⁴²⁹ and alefacept, an agent that reduces CD45RO-positive T cells.⁴³⁰ Newer treatments that may show promise include the recombinant IL-10 agent ilodecakin,⁴³¹ ABT-874 (an IL-12/23

Figure 4.1 Psoriasis. (A) A very early lesion with dilated vessels in a dermal papilla, perivascular cuffing with lymphocytes, and exocytosis of lymphocytes and a neutrophil or two. (B) A slightly later stage with neutrophils migrating to the summits of the parakeratotic mounds. (C) Dilated vessels are in the papillary dermis. (H&E)

monoclonal antibody),⁴³² botulinum toxin type A for flexural psoriasis;¹³¹ oral bexarotene, a synthetic retinoid X receptor;⁴³³ paclitaxel;⁴³⁴ everolimus, a rapamycin-derived macrolide;⁴³⁵ the thiazolidinediones; and new-generation, all-*trans* retinoic acid metabolism blocking agents (RAMBAs).⁴³⁶

Histopathology^{2,115,437–440}

Psoriasis is a dynamic process and consequently the histopathological changes vary during the evolution and subsequent resolution of individual lesions. The earliest changes, seen in lesions of less than 24 hours' duration, consist of dilatation and congestion of vessels in the papillary dermis and a mild, perivascular, lymphocytic infiltrate, with some adjacent edema. There is also some exocytosis of lymphocytes into the epidermis overlying the vessels, and this is usually associated with mild spongiosis (Fig. 4.1). The epidermis is otherwise normal. This is soon followed by the formation of mounds of parakeratosis, with exocytosis of neutrophils through the epidermis to reach the summits of these parakeratotic foci.⁴⁴¹ There is often overlying orthokeratosis of normal basket-weave type and loss of the underlying granular layer. At this papular stage, increased mitotic

activity can be seen in the basal layer of the epidermis associated with a modest amount of psoriasiform acanthosis (Fig. 4.2). Keratinocytes in the upper epidermis show some cytoplasmic pallor. Blood vessels in the papillary dermis are still dilated and somewhat tortuous, and their lumen may contain neutrophils. Lymphatic channels are also increased.⁴⁴² Very few neutrophils are ever present in the perivascular infiltrate: this consists mainly of lymphocytes, Langerhans cells, and indeterminate cells.⁴⁴³ A few extravasated erythrocytes may also be present. These changes can also be seen in guttate psoriasis, although the epidermal hyperplasia is usually mild in this variant of psoriasis.²

In early plaques of psoriasis and in 'hot spots' of more established plaques,⁴⁴⁴ there are mounds of parakeratosis containing neutrophils, which usually migrate to the upper layers (summits) of these mounds (Fig. 4.3). With time, confluent parakeratosis develops (Fig. 4.4). Several layers of parakeratosis containing neutrophils, with intervening layers of orthokeratosis, are sometimes present. Although intracorneal collections of neutrophils (Munro microabscesses) are common, similar collections in the spinous layer (spongiform pustules of Kogoj) are less so. They are also much smaller than in pustular psoriasis. Munro microabscess can also be detected by reflectance confocal laser

Figure 4.2 Psoriasis. Mitoses are evident in keratinocytes within the epidermis. (H&E)

Figure 4.4 Psoriasis. Confluent parakeratosis overlies an epidermis showing psoriasiform hyperplasia. (H&E)

Figure 4.3 Psoriasis. (A) There is psoriasiform hyperplasia of the epidermis. (B) Neutrophils are present in the upper layers of the overlying parakeratotic scale – neutrophils migrating to the 'summits' of the parakeratotic mounds. (H&E)

microscopy, a noninvasive technique that can also be used to demonstrate parakeratosis and tortuous papillary dermal capillaries.⁴⁴⁵ These pustules contain lymphocytes in addition to neutrophils. The epidermis now shows psoriasiform (regular) hyperplasia, with relatively thin suprapapillary plates overlying the dilated vessels of the papillary dermis (Fig. 4.5A). Ki-67 expression is increased.⁴⁴⁶ A few mononuclear cells are usually present in the lower layers of the suprapapillary epidermis. The dermal inflammatory cell infiltrate is usually slightly heavier than in earlier lesions. It includes activated T lymphocytes,⁴⁴⁷ fewer Langerhans cells than in earlier lesions, and very occasional neutrophils.⁴⁴³ A subset of spindle-shaped macrophages, situated along the basement membrane, has been described as a characteristic feature. These so-called 'lining cells' are positive for CD11c. There are increased numbers of dermal macrophages in psoriatic skin, a number of these being CD163-positive; these probably contribute to the pathogenesis of the disease through the release of inflammatory mediators.⁴⁴⁸ Plasma cells and eosinophils are usually absent,⁴³⁹ but eosinophil cationic protein has been identified, particularly in the upper third of the epidermis in psoriasis.⁴⁴⁹ Plasma cells may be present in patients with HIV infection.⁴⁵⁰

With time, there may be club-shaped thickening of the lower rete pegs with coalescence of these in some areas (Fig. 4.5B).^{439,440} Later lesions show orthokeratosis, an intact granular layer, and some thickening of the suprapapillary plates. Exocytosis of inflammatory cells is usually mild. The finding of numerous fatty vacuoles in the papillary dermis – pseudolipomatosis cutis (see p. 1018) – is of doubtful significance.^{451,452} The phenomenon has not been satisfactorily explained.⁴⁵² Differentiation of late lesions of psoriasis from lichen simplex chronicus may be difficult, although in the latter condition the suprapapillary plates and granular layer are usually more prominent and there may be vertically oriented collagen bundles in the papillary dermis.² If psoriatic plaques are rubbed or scratched, the histopathological features of the underlying psoriasis may be obscured by these superimposed changes.

The term '*psoriatic neurodermatitis*' has been proposed for pruritic, lichenified plaques on the elbows and/or knees.⁴⁵³ Lesions were more numerous, smaller, more keratotic, and less excoriated than in typical lichen simplex chronicus. Microscopically, the lesions showed micro-abscesses in the horny layer, hypogranulosis, regular acanthosis, and thinning of the suprapapillary plates.⁴⁵³ It is thought that these cases represent psoriasis with superimposed lichen simplex chronicus.⁴⁵³

Figure 4.5 Psoriasis. (A) The dilated vessels in the papillary dermis are well shown. The suprapapillary epidermis ('plate') is relatively thin. (B) There is some coalescence of the tips of the rete pegs. (H&E)

In resolving or treated plaques of psoriasis, there is a progressive diminution in the inflammatory infiltrate, a reduction in the amount of epidermal hyperplasia, and restoration of the granular layer.⁴³⁷ Vessels in the papillary dermis are still dilated, although by now there is an increase in fibroblasts in this region with mild fibrosis.⁴³⁷ Only after 10–14 weeks of treatment do the histological appearances return to normal.⁴⁵⁴

Minor changes that have been reported in psoriasis of the scalp include sebaceous gland atrophy, a decrease in hair follicle size, and thinner hair shafts.^{455,456} Other features of scalp psoriasis include dilatation of infundibula with parakeratosis at the lips of the infundibular ostia, papillomatosis, and scattered apoptotic keratinocytes.⁴⁵⁶ Munro microabscesses are said to be uncommon in this region.⁴³⁹ Another regional variation is the lessened epidermal hyperplasia in psoriasis of the penis and vulva;⁴³⁹ spongiosis may be present.

Spongiosis has already been mentioned as a feature of the early lesions of psoriasis and of psoriasis occurring in various regions, such as the hands and feet and genital regions. It may also occur in erythrodermic psoriasis (see later). Ackerman has also drawn attention to its presence in other situations (see p. 132). The author has seen several cases that caused diagnostic confusion, initially because of significant spongiosis, but that, over time, have evolved into classic psoriasis. Their initial biopsies showed spongiosis, mounds of para-

Figure 4.6 Psoriasis. There is mild spongiosis at the tips of the rete pegs. (H&E)

keratosis containing neutrophils, dilated vessels in the papillary dermis, and a mild, superficial perivascular infiltrate of lymphocytes. The term *spongiotic psoriasis* is an appropriate designation for these cases (Fig. 4.6).

The nail plate in nail psoriasis shows hyperkeratosis, focal parakeratosis, and variable neutrophil exocytosis into the parakeratotic layer. Spongiosis is a common feature of nail psoriasis.¹⁹ Examination of PAS-stained sections is necessary before making a diagnosis of nail psoriasis because onychomycosis and psoriasis may show similar histology.¹⁹

In *erythrodermic psoriasis*, the appearances may resemble those described in early lesions of psoriasis, possibly a reflection of the early medical intervention that usually occurs in this condition.⁴⁵⁷ Dilatation of superficial vessels is usually quite prominent. A cornified layer is usually absent. Sometimes the histological changes do not resemble those of psoriasis at all.

In *follicular psoriasis*, there is follicular plugging with marked parakeratosis in the mid-zone of the ostium.¹³² The dermal inflammatory infiltrate is both perivascular and perifollicular.

In *annular verrucous psoriasis*, there is exaggerated papillomatosis resulting in finger-like projections of the epidermis.¹⁴⁰ Similar changes have been reported in cases called 'verrucous psoriasis'. The papillomatosis and bowing of the peripheral rete ridges toward the center of the lesion mimic the appearances of verruca vulgaris.¹⁴¹

Skin tumors have developed at sites treated with PUVA therapy,^{458,459} particularly after prolonged exposure.^{79,460,461} Prolonged UVB therapy results in the accumulation of DNA photoproducts in the cells, although adaptive responses occur.⁴⁶² The use of coal tar does not produce any appreciable increase in skin cancers.⁴⁶³ Variants of seborrheic keratosis have also been reported in psoriatic patients receiving treatment with ultraviolet radiation.⁴⁶⁴ Of relevance is the controversy regarding whether patients with psoriasis have an inherently low risk of developing skin cancer,^{465,466} although recent studies suggest that this is not so.^{467–469} Psoriasis may protect against the development of actinic keratoses.^{466,470} Another rare complication of treatment is cutaneous ulceration, which has been reported following methotrexate therapy.⁴⁷¹

Differential diagnosis

The histopathological differentiation of psoriasis from *chronic eczematous dermatitis*, particularly seborrheic dermatitis, is sometimes difficult.⁴⁷² The presence of prominent spongiosis involving the rete ridges generally rules out psoriasis, whereas the presence of a leukocytic exudate, other than in a folliculocentric distribution, is quite

uncommon in seborrheic dermatitis.¹ In seborrheic dermatitis, there is often less epidermal hyperplasia than in psoriasis. Spongiotic psoriasis (discussed previously) can be very difficult to distinguish from other spongiotic processes. The presence of mounds of parakeratosis containing neutrophils and a dermal infiltrate that is usually mild are clues to the diagnosis of psoriasis.

Distinguishing palmoplantar psoriasis from an eczematous dermatitis at these sites can be difficult because they share some histological features. A study found that the presence of multiple parakeratotic foci, placed vertically and alternating with orthohyperkeratosis, favored a diagnosis of psoriasis.⁴⁷³ Psoriasis in this site often shows spongiosis, but it is often restricted to the lower epidermis. Spongiotic vesicles were present in approximately 75% of cases in this series.⁴⁷³ Neutrophils and/or plasma are often present in the parakeratotic layers in palmoplantar psoriasis, but it is very uncommon for the neutrophils to be at the summits of the parakeratotic mounds.⁴⁷³

The features that distinguish psoriasis from *lichen simplex chronicus* were discussed previously. Spongiosis is sometimes present in the rete ridges in this latter condition if it is superimposed on an eczematous process. Psoriatic neurodermatitis needs consideration (discussed previously).⁴⁵³

Well-developed spongiform pustulation is a feature that favors psoriasis and a limited number of other conditions: Reiter's syndrome, geographic tongue, candidiasis, and sometimes necrolytic migratory erythema. Other conditions that show psoriasiform acanthosis, such as *digitate dermatosis* and *pityriasis rubra pilaris*, lack neutrophilic aggregates and usually fail to show the degree of acanthosis seen in fully developed plaque lesions of psoriasis. In *pityriasis rubra pilaris*, there is mild to moderate psoriasiform hyperplasia, parakeratotic lipping of follicles, and, in some lesions, alternating zones of orthokeratosis and parakeratosis in both horizontal and vertical directions.

Pustular psoriasis has more prominent spongiform pustulation than psoriasis vulgaris, particularly at the shoulders of the lesions.

Electron microscopy⁴⁷⁴

There are numerous cytoplasmic organelles in the keratinocytes, reflecting their hyperactivity. These are decreased with treatment.⁴⁷⁵ Tonofilaments and desmosomes are reduced in number and size, and there is also a reduction in the number of keratohyaline granules.⁴⁷⁴ Vessels in the papillary dermis are dilated with abundant fenestrations.⁴⁷⁴ Neutrophils are said to be polar in shape with ruffled cell membranes.⁴⁷⁶

PSORIASIFORM KERATOSIS

Psoriasiform keratosis is the name given by Walsh, Hurt, and Santa Cruz to lesions that closely mimic psoriasis in the same way that the term lichenoid keratosis is used for solitary lesions with a resemblance to lichen planus.⁴⁷⁷ Psoriasiform keratoses are usually solitary lesions on the extremities of elderly persons who have no other clinical features of psoriasis at the time of presentation or on subsequent follow-up examination.^{477,478} Other sites of involvement have been the scalp, neck, shoulders, and back.⁴⁷⁷ Clinically, the lesions resemble a seborrheic keratosis, basal cell carcinoma, actinic keratosis, or Bowen's disease. A diagnosis of psoriasis is only occasionally made.

The lesions are usually well-defined, scaly plaques that vary in size from 0.5 to 3 cm in diameter.

Histopathology

The microscopic features resemble psoriasis but with more parakeratosis and less psoriasiform hyperplasia (for the amount of parakeratosis) than is usual in most cases of chronic psoriasis (Fig. 4.7). This imparts a vague resemblance to a seborrheic keratosis. The parakera-

Figure 4.7 Psoriasiform keratosis. There is a close resemblance to psoriasis, but this was a solitary lesion on the leg of an elderly male with no history of psoriasis. The parakeratosis is sometimes prominent.

tosis is often diffuse, but it may be focal.⁴⁷⁸ There are intracorneal collections of neutrophils, often arranged in vertical tiers.⁴⁷⁷ There may be mild spongiosis.

The dermis shows a mild to moderate superficial perivascular infiltrate of lymphocytes. Some vascular proliferation is often present, but this may be a reflection of the anatomic site (lower legs) of many lesions. Human papillomavirus type 6 was detected in one lesion using polymerase chain reaction technology.⁴⁷⁹

The PAS stain is negative for fungal organisms.

AIDS-ASSOCIATED PSORIASIFORM DERMATITIS

Psoriasis, seborrheic dermatitis and cases with overlap features may occur in patients infected with the human immunodeficiency virus (HIV).⁴⁸⁰⁻⁴⁸³ The term 'AIDS-associated psoriasiform dermatitis' has been used, particularly for those cases with features of both conditions. Interestingly, there is often more uniformity in the histopathological expression than in the clinical presentations. In some circumstances, onset of the disease, or its exacerbation, has been associated with the initial seroconversion. In others, exacerbations are associated with cutaneous or systemic infections. The severity of the disease is variable. A Reiter's syndrome-like pattern has been seen in this condition.⁴⁸⁴ There are differences in epidermal expression of heat shock proteins HSP65 and HSP72 in AIDS-associated psoriasiform dermatitis compared to that in psoriasis, seborrheic dermatitis, and normal skin in non-HIV-infected patients. These differences include intensity (less intense expression in AIDS-associated psoriasiform dermatitis) and distribution and cellular pattern of expression.³⁹⁵ The authors postulate that the differences could be explained by altered interaction of T cells and keratinocytes in states of immune dysregulation such as AIDS.³⁹⁵

Histopathology

The epidermis shows psoriasiform hyperplasia, but unlike psoriasis, there is no thinning of the suprapapillary plate. There are scattered apoptotic keratinocytes within the epidermis, usually associated with some lymphocyte exocytosis. Perivascular lymphocytes in the dermis may show karyorrhexis, giving rise to small amounts of nuclear dust. Plasma cells are often present in small numbers.⁴⁵⁰

PUSTULAR PSORIASIS

Pustular psoriasis is a rare, acute form of psoriasiform dermatosis characterized by the widespread eruption of numerous sterile pustules on an erythematous base and associated with constitutional symptoms.^{120,485-487} Skin tenderness, a neutrophil leukocytosis, and an absolute lymphopenia⁴⁸⁸ may precede the onset of the pustules. These may continue to develop in waves for several weeks or longer before remitting. Arthritis,⁴⁸⁹ generalized erythroderma,⁴⁸⁹ hypocalcemia,^{490,491} and lesions of the mucous membranes, including fissured tongue and benign migratory glossitis (geographical tongue), may develop in the course of the disease.⁴⁹² Amyloidosis,⁴⁹³ acute respiratory distress syndrome,⁴⁹⁴⁻⁴⁹⁶ and a bullous disorder⁴⁹⁷ are extremely rare complications. Erythema gyratum repens has developed in resolving pustular psoriasis.⁴⁹⁸

Several clinical variants of pustular psoriasis are recognized.^{485,489} The **Von Zumbusch type** (generalized pustular psoriasis) is the most common variant. It has an explosive onset and a mortality rate as high as 30% in some of the earlier series. **Impetigo herpetiformis** is a controversial entity defined by some on the basis of flexural involvement with centripetal spread of the pustules and by others as a variant of pustular psoriasis occurring in pregnancy.⁴⁹⁹⁻⁵⁰³ As such, it is a rare pruritic dermatosis of pregnancy; fewer than 150 cases have been reported.⁵⁰⁴ Onset in pregnancy is usually in the third trimester, although it develops earlier in subsequent pregnancies.⁵⁰⁵⁻⁵⁰⁷ It usually remits postpartum, but it may flare with the use of oral contraceptives.⁵⁰⁸ Menstrual exacerbations that occurred for 7 years postpartum have been reported in one patient.⁵⁰⁹ Fetal mortality is high as a consequence of placental insufficiency.⁵⁰⁸ A subset related to hypoparathyroidism with hypocalcemia is sometimes included in impetigo herpetiformis.⁵¹⁰⁻⁵¹² Hyperparathyroidism was present in one case.⁵¹³ Impetigo herpetiformis has been followed by generalized pustular psoriasis, suggesting that it is part of the pustular psoriasis spectrum and not a distinct entity.⁵¹⁴ The **acral variant** of pustular psoriasis arises in a setting of acrodermatitis continua, which is a localized pustular eruption of one or more digits with displacement and dystrophy of the nails.^{485,515-518} It has been caused by oral terbinafine.⁵¹⁹ The development of generalized pustular psoriasis in acrodermatitis continua has a poor prognosis.^{485,515} Palmoplantar pustulosis is associated with plaque psoriasis in approximately 20% of cases. It is sufficiently distinct in its clinical, genetic, and biological features to be regarded as a separate entity, distinct from psoriasis (see p. 147).^{15,520,521} Other variants include an *exanthematic form*,^{485,515,522} *diaper pustular psoriasis*,⁵²³ an *annular variant*,⁵²⁴⁻⁵²⁶ with some resemblance to subcorneal pustular dermatosis, a *linear variant*,^{527,528} and a *localized form* that consists of pustular psoriasis developing in pre-existing plaques of psoriasis.^{485,489} The annular variant is the most common form of pustular psoriasis in children,⁵²⁶ although generalized pustular psoriasis has also occurred in childhood.⁵²⁹ Some of the cases reported in the past as exanthematous variants may represent examples of acute generalized exanthematous pustulosis (see p. 145).⁵³⁰ A case of pustular psoriasis limited to the penis has been reported.⁵³¹ There was no pre-existing condition. Pustular psoriasis developing over keloids may be an example of the Koebner phenomenon.⁵³²

Generalized pustular psoriasis may develop in three main clinical settings.⁴⁸⁵ In the first group, there is a long history of psoriasis of early onset. In these cases, the pustular psoriasis is often precipitated by some external provocative agent (see later). In the second group, there is preceding psoriasis of atypical form in which the onset was relatively late in life. Precipitating factors are not usually present. In the third group, pustular psoriasis arises without pre-existing psoriasis. Pustular psoriasis may rarely develop as a consequence of persistent pustulosis of the palms and soles. Familial cases of pustular psoriasis^{533,534} and onset in childhood have also been reported.⁵³³⁻⁵³⁷ In children, pustular

Table 4.3 Factors/drugs implicated in precipitating pustular psoriasis

Aceclofenac	Malignancy
Alcohol	Morphine
β-Blockers	NSAIDs
Bupropion	Nystatin
Burns	PEGylated IFN-α-2b
Calcipotriol	Penicillin and derivatives
Clopidogrel	Phenylbutazone
Corticosteroid withdrawal	Prednisolone
Cyclosporine and its withdrawal	Pregnancy
Doxorubicin	Procaine
Emotional stress	Progesterone
Endocrine/metabolic factors	Sorafenib
Hydroxychloroquine	Sulfonamides
Infections	Sunlight
Infliximab	Tanning salons
Iodides	Terbinafine
Lithium	TNF inhibitors

psoriasis can be complicated by sterile, lytic lesions of bones.^{536,538} The development of renal failure and cholestatic jaundice in one patient may have been a coincidence.⁵³⁹

Numerous factors have been implicated in precipitating pustular psoriasis,⁵⁴⁰ including infections, sunlight, burns,⁵⁴¹ ultraviolet radiation from tanning salon use,⁵²⁵ alcohol, malignancy, metabolic and endocrine factors, pregnancy,⁵⁴² emotional stress, and drugs. The drugs include lithium,⁵⁴³ iodides, clopidogrel,⁵⁴⁴ nonsteroidal anti-inflammatory agents including phenylbutazone⁵⁴⁵ and aceclofenac,⁵⁴⁶ β-blockers,⁵⁴⁷ penicillin and related drugs,⁵⁴⁰ procaine, cyclosporine,^{548,549} and, following its withdrawal after short-term use,⁵⁵⁰ infliximab⁵⁵¹ and other TNF inhibitors,⁵⁵² oral terbinafine,^{553,554} bupropion,⁵⁵⁵ prednisolone,⁵⁵⁶ sulfonamides, doxorubicin,⁵⁵⁷ morphine, hydroxychloroquine, progesterone,⁵⁵⁸ nystatin, topical calcipotriol,^{559,560} sorafenib,⁵⁶¹ and PEGylated IFN-α-2b.⁵⁶² The withdrawal of steroids is a common precipitating factor that may be included in this category. The various agents that may precipitate pustular psoriasis are listed in Table 4.3. Generalized pustular psoriasis has developed in patients with bullous and nonbullous ichthyosiform erythroderma.⁵⁶³

One of the most striking features of pustular psoriasis is the enhanced chemotaxis of neutrophils, which is even more marked than in psoriasis.^{564,565} The chemotactic factors in the affected areas of skin include leukotrienes, complement products, and cathepsin 1.⁵⁶⁶ Recent investigations have shown that alteration of structure and function of an IL-36 receptor antagonist (IL36RN) leads to unregulated inflammatory cytokine secretion and the development of generalized pustular psoriasis.⁵⁶⁷⁻⁵⁶⁹ Recessively inherited mutations of the *IL36RN* gene have been assigned the acronym DITRA.⁵⁷⁰ A homozygous missense mutation in the *IL36RN* gene has also been found in a patient with acrodermatitis continua of Hallopeau.⁵⁷¹

The treatment options for *pustular psoriasis* include phototherapy, photochemotherapy, retinoids, and immunosuppressive therapy,⁵⁷² infliximab and etanercept,⁵⁷³⁻⁵⁷⁵ cyclosporine⁵⁷⁶ (although cessation of cyclosporine has produced flares of pustular psoriasis⁵⁷⁷), and methotrexate. Topical treatments have included corticosteroids, tar, dithranol, fluorouracil, calcipotriol, and topical tacrolimus 0.1% ointment.⁵⁷⁸ Other systemic therapies, with or without topical therapy, have included colchicine, dapsone, corticosteroids, oral propylthiouracil combined with methotrexate,^{576,578} adalimumab,⁵⁷⁹ anakinra (an IL-1

Figure 4.8 Early pustular psoriasis. There is a heavy infiltrate of neutrophils in the upper layers of the epidermis and beneath the stratum corneum. (H&E)

Figure 4.9 Pustular psoriasis (old lesion). There is pronounced psoriasiform hyperplasia of the epidermis and spongiform pustulation in the upper layers. (H&E)

receptor antagonist),⁵⁸⁰ and ustekinumab⁵⁸¹ (although there has been one report of a flare of pustular psoriasis following initiation of ustekinumab therapy).⁵⁸²

Histopathology^{583,584}

The diagnostic feature is the presence of intraepidermal pustules at various stages of development (Fig. 4.8). In early lesions, the epidermis is usually only slightly acanthotic, whereas psoriasiform hyperplasia is seen only in older and persistent lesions (Fig. 4.9). Mitoses are usually present within the epidermis. Neutrophils migrate from dilated vessels in the papillary dermis into the epidermis. They aggregate beneath the stratum corneum and in the upper malpighian layer between degenerate and thinned keratinocytes to form the so-called 'spongiform pustules of Kogoj' (Fig. 4.10).⁵⁸⁵ The subcorneal pustules have a thin roof of stratum corneum. In later lesions, these are replaced by scale crusts with collections of neutrophils trapped between parakeratotic layers. A few eosinophils may be present in the infiltrate.

The blood vessels in the papillary dermis are usually dilated, and there is a perivascular infiltrate of lymphocytes and a few neu-

Figure 4.10 Pustular psoriasis. A spongiform pustule of Kogoj is shown. (H&E)

trophils. Large mononuclear cells were noted in the pustules and in the dermis in one report of impetigo herpetiformis.⁵⁸⁶ They were thought to be specific for this variant of pustular psoriasis, although they were specifically excluded in a subsequent report of this condition.⁵⁸⁶ There is some overlap of the microscopic features of pustular psoriasis with those of acute generalized exanthematous pustulosis (AGEP), although the latter tends to have smaller intraepidermal pustules and may also show apoptosis and underlying vasculitic changes. One study showed comparable increases in immunostaining for the proliferation marker Ki-67 in pustular psoriasis and AGEP, suggesting that epidermal proliferation may be important in both diseases.⁵⁸⁷

Electron microscopy⁵⁶⁶

Multipolypoid herniations of basal keratinocytes have been described protruding into the dermis through large gaps in the basal lamina. Neutrophil proteases are probably responsible for this change. In another study, there were gaps between the endothelial cells of dermal blood vessels.⁵⁸⁸

REITER'S SYNDROME

Reiter's syndrome is usually defined as the triad of nongonococcal urethritis, ocular inflammation, and arthritis.⁵⁸⁹ The presence of mucocutaneous lesions is sometimes included as a fourth feature.⁵⁹⁰ Reiter's syndrome occurs in approximately 30% of patients with reactive arthritis, which in turn develops in 1–3% of patients with sexually acquired, nongonococcal infections of the genital tract.^{589,591} Reiter's syndrome has also been associated with certain bacterial gut infections, including those due to *Shigella flexneri*, *Yersinia enterocolitica*,⁵⁹² and, rarely, *Campylobacter jejuni*.⁵⁹³ The genital infectious agent that is usually incriminated is *Chlamydia trachomatis*, but *Ureaplasma urealyticum* and species of *Mycoplasma* have also been isolated.^{589,593} Chlamydial elementary bodies have been detected by immunofluorescence and monoclonal antibodies in the synovium of patients with reactive arthritis, which to date has always been sterile by conventional cultures.⁵⁹⁴ *Chlamydia*-specific antigens have been detected in a biopsy of the cutaneous lesions of Reiter's syndrome.⁵⁹⁵ Reiter's syndrome has also been induced by systemic IFN- α treatment⁵⁹⁶ and by adalimumab in combination with leflunomide.⁵⁹⁷ Exacerbation by lithium has been reported.⁵⁹⁸

There is genetic susceptibility to the development of reactive arthritis and Reiter's syndrome, and this is manifest by the presence of the

histocompatibility antigen HLA-B27.^{592,599} Other clinical features of Reiter's syndrome include a marked preponderance in males, a mean age of onset in the third decade of life, and a variable, often relapsing course.⁵⁹⁹⁻⁶⁰¹ Some cases begin in childhood.⁶⁰² An association with AIDS has been reported.^{603,604}

The mucocutaneous lesions, already alluded to, include a circinate balanitis with perimeatal erosions and mucosal ulcers.⁶⁰⁵ An ulcerative vulvitis is rarely present.^{606,607} In 10–30% of cases, there are crusted erythematous papules and plaques with a predilection for the soles of the feet, genitalia, perineum, buttocks, scalp, and extensor surfaces of the extremities.⁶⁰¹ Some lesions may be frankly pustular, resembling pustular psoriasis. These cutaneous lesions are known by the term 'keratoderma blennorrhagica'. They usually heal after several weeks, without scarring. Nail changes can also occur.⁶⁰⁸ Ackerman believes that Reiter's syndrome is a variant of psoriasis.⁶⁰⁹

The eponym 'Reiter's syndrome' is declining in use in the medical literature, possibly because Reiter, a physician leader of the Nazi party, authorized medical experiments on prisoners of concentration camps.⁶¹⁰ Nevertheless, it was used in a major review of the subject.⁶¹¹

Histopathology

In most biopsies, the cutaneous lesions of Reiter's syndrome are indistinguishable from pustular psoriasis. Accordingly, there is psoriasiform epidermal hyperplasia with a thick horny layer (Fig. 4.11). This is most prominent in lesions on the palms and soles and least prominent in penile and buccal lesions. Spongiform pustulation with exocytosis of neutrophils is another conspicuous feature.⁶¹² A variable inflammatory cell infiltrate, usually including a few neutrophils, is present in the upper dermis.⁶¹³ A mild, leukocytoclastic vasculitis has been observed in the papillary dermis of several cases.⁵⁹⁵

Differential diagnosis

Various histological features have been claimed to be more suggestive of Reiter's syndrome than pustular psoriasis. These include a thicker horny layer, larger spongiform pustules, eczematous changes, a thicker suprapapillary plate of epidermis, the presence of neutrophils in the dermis, and the absence of clubbing of the rete ridges. The horny layer is sometimes more loosely attached than in pustular psoriasis, leading to its partial detachment during processing of the specimen. These various features are usually not sufficiently different from the findings

Figure 4.11 Reiter's syndrome. The appearances may be indistinguishable from pustular psoriasis. (H&E)

in pustular psoriasis to allow a confident distinction to be made between the two conditions on biopsy material.

PITYRIASIS RUBRA PILARIS

Pityriasis rubra pilaris (PRP) is a rare, erythematous squamous dermatosis of unknown etiology with a prevalence that varies from 1 in 5000 to 1 in 50,000 in various populations.⁶¹⁴ It is characterized by small follicular papules with a central keratin plug, perifollicular erythema with a tendency to become confluent but with islands of sparing, palmoplantar keratoderma, often with edema, and pityriasis capitis.⁶¹⁵⁻⁶¹⁹ The condition often begins with a seborrheic dermatitis-like rash on the face or scalp that rapidly spreads downwards.⁶²⁰⁻⁶²⁴ In other patients, particularly juveniles, the disease starts on the lower half of the body.^{625,626} Some patients may become erythrodermic.⁶²⁷⁻⁶³⁰ Exacerbation of PRP with ultraviolet exposure is well recognized; much less common is its presentation in a photoexposed distribution.⁶³¹ A variable degree of pruritus is often present.⁶³² Cases with localized lesions, often restricted to the elbows and knees, occur.⁶³³ The thigh is another site for localized disease.⁶³⁴ There are several reports of evolution of PRP to an eruption resembling erythema gyratum repens.⁶³⁵ Severe forms of PRP have been reported in patients infected with HIV.⁶³⁶⁻⁶⁴⁰ In accord with the clinical classification of Griffiths (see later), it has been proposed that HIV-related PRP be considered a candidate for 'type VI' disease.⁶⁴¹ Cystic acne may coexist.⁶³⁷ Arthropathy and osteoporosis have been present in another patient with PRP,⁶⁴² and an association with arthritis has also been reported.⁶⁴³

Pityriasis rubra pilaris has been reported as the initial manifestation of internal neoplasia.⁶⁴⁴⁻⁶⁴⁶ Its association with Down syndrome may be fortuitous.⁶⁴⁷ Rarely, dermatomyositis may present with a PRP-like eruption,⁶⁴⁸ and there has been a report of coexistence of PRP and systemic sclerosis. A rare familial form with suggested autosomal dominant inheritance occurs.⁶⁴⁹

Nail changes,^{615,650} alopecia,^{616,617} and, rarely, multiple seborrheic keratoses or cutaneous malignancies may occur in patients with pityriasis rubra pilaris.^{651,652} Hypothyroidism is a rare association,⁶⁵³ as is membranous nephropathy.⁶⁵⁴ The age of onset and clinical course are quite variable.⁶⁵⁵⁻⁶⁵⁸ For this reason, the clinical classification into five types, as proposed by Griffiths, has not been used here.⁶⁵⁹ Remission occurs within 6 months to 2 years in approximately 50% of cases,^{614,660,661} but recurrences occur in more than 10% of cases.^{657,662}

Although there is some resemblance to vitamin A deficiency (phrynodema), serum vitamin A levels are normal.⁶²⁷ Reduced levels of retinol-binding protein (the specific carrier of vitamin A) have been reported,⁶⁶³ but the results of this work have not been confirmed.^{664,665} Epidermal cell kinetics show an increased rate of cell proliferation.^{666,667} It has been suggested that the acute juvenile form of PRP is a superantigen-mediated disease.⁶²³ In the autosomal dominant form of the disease, several different heterozygous mutations have been found involving *CARD14*, which encodes an activator of NF- κ B signaling known to be involved in inflammatory disorders. Mutations of *CARD14* have also been found in familial psoriasis.⁶⁶⁸

Treatments include topical retinoids, either tazarotene gel or tretinoin 0.05% cream,^{634,669} topical corticosteroids,⁶⁵⁸ topical calcipotriol and tar, oral retinoids (which may be beneficial for more widespread disease),^{614,647,657,670} vitamin D analogs, cyclosporine,⁶²⁴ methotrexate, azathioprine, narrowband UVB, intravenous immunoglobulin,⁶⁷¹ infliximab,^{670,672,673} ustekinumab,⁶⁷⁴ adalimumab,⁶⁷⁵ extracorporeal photopheresis,⁶³⁰ and etanercept alone or in combination with oral acitretin.⁶⁷⁶ Demonstrable upregulation of TNF- α explained the response to adalimumab in one case.⁶⁷⁷ One patient with PRP treated with ustekinumab developed CD30-positive anaplastic large cell T-cell lymphoma.⁶⁷⁸ Sorafenib has been reported to produce an eruption that resembles PRP.⁶⁷⁹

Histopathology^{2,627,680}

The changes are most marked when erythema is greatest, and they are least impressive in biopsies of follicular papules.⁶¹⁸ There is diffuse orthokeratosis with spotted parakeratosis that also forms a collarette around the follicular ostia (Fig. 4.12). Some follicular plugging is often present (Fig. 4.13).⁶⁸¹ Parakeratosis is not prominent in early lesions.

Figure 4.12 Pityriasis rubra pilaris. (A) As it should be, with psoriasiform hyperplasia and overlying 'geometric' parakeratosis. (B) High-power view of the case shown in A. (C) There is a very thick parakeratotic and orthokeratotic scale. Not too many conditions give such a thick scale. (H&E)

These changes may be stated in another way – alternating orthokeratosis and parakeratosis in both vertical and horizontal directions (Fig. 4.14).⁶⁸⁰ However, many cases will be missed if this criterion is too rigidly applied (Fig. 4.15). There is also acanthosis: this is never as regular as that seen in psoriasis. There are broad rete ridges and thick suprapapillary plates. Hypergranulosis is often prominent, and this may be focal or confluent.⁶⁸⁰ An unusual perinuclear vacuolization is sometimes seen in cells in the malpighian layer, and there may be some vacuolar change involving the pilary outer root sheath. Spongiosis, usually mild, is present in approximately 10% of cases.^{670,682} There is a superficial perivascular and perifollicular lymphocytic infiltrate in the dermis. Although the infiltrate is usually mild, a heavy infiltrate, which is rarely lichenoid in distribution, is sometimes present.⁶⁸³ Eosinophils and plasma cells are occasionally present in the infiltrate.⁶⁸⁴ Folliculitis is a rare complication.⁶⁵⁶ Focal acantholytic dyskeratosis has been found in PRP and may be more common than previously thought (Fig. 4.16).^{652,685–689} One such case was complicated by Kaposi's varicelliform eruption due to herpes simplex infection.⁶⁹⁰ Epidermolytic hyperkeratosis has been reported in one case.⁶⁸⁶

Confocal reflectance microscopy has been used successfully to support the histopathologic findings in PRP; in particular, alternating ortho- and parakeratosis, lack of neutrophils, preservation of the granular layer, and irregular dermal papillae are features that can be discerned with this method.⁶⁹¹

Electron microscopy

Tonofilaments and desmosomes are decreased, but there are large numbers of keratinosomes and lipid-like vacuoles in the parakeratotic areas.⁶⁹² The basal lamina is focally split, containing gaps.⁶⁹²

Differential diagnosis

In contrast to pityriasis rubra pilaris, vitamin A deficiency shows no focal parakeratosis, irregular acanthosis, or dermal inflammatory infiltrate.⁶¹⁶ The microscopic differential diagnosis includes *psoriasis*, but PRP tends to show modest degrees of acanthosis while lacking the thinning of suprapapillary plates or the neutrophilic infiltration expected in psoriasis. Although psoriasis can show vertically oriented parakeratosis alternating with orthokeratosis, the 'checkerboard' configuration of PRP is not observed. When present, acantholysis would argue against psoriasis, which does not display that feature. PRP can

Figure 4.13 Pityriasis rubra pilaris. Keratotic follicular plugging and lipping are demonstrated in this image. (H&E)

Figure 4.14 Pityriasis rubra pilaris. (A) There is alternating orthokeratosis and parakeratosis in both a horizontal and a vertical direction. (B) and (C) High-power views of other cases of this condition. (H&E)

Figure 4.15 Pityriasis rubra pilaris. The diagnosis of cases such as this can be difficult. The author misses more cases of this condition (on the initial biopsy) than any other. (H&E)

Figure 4.16 Pityriasis rubra pilaris. Acantholysis is a well-documented but often unexpected finding.

also resemble other lesions showing modest acanthosis, including *chronic spongiotic dermatitis* or *parapsoriasis* (digitate dermatosis). Spongiosis is generally not observed in PRP, but when lesions in the 'spongiotic' category lack significant spongiotic change on microscopic examination, differentiation may be quite difficult. Horizontal and vertical alternating ortho- and parakeratosis would not be expected in conditions other than PRP; unfortunately, this feature is not always present, but extra levels from the paraffin block are sometimes useful to demonstrate the finding. Follicular hyperkeratosis with shouldered parakeratosis may be an additional feature pointing to a diagnosis of PRP, but this could potentially be mimicked in individuals with atopic dermatitis with follicular involvement or in patients with keratosis pilaris.

PARAPSORIASIS

The term 'parapsoriasis', as originally introduced, referred to a heterogeneous group of asymptomatic, scaly dermatoses with some clinical

resemblance to psoriasis.^{693–695} These conditions were further characterized by chronicity and resistance to therapy. Three distinct entities are now recognized as having been included in the original concept of ‘parapsoriasis’ – pityriasis lichenoides, chronic superficial dermatitis (small plaque parapsoriasis and digitate dermatosis), and large plaque parapsoriasis (atrophic parapsoriasis, retiform parapsoriasis, and patch-stage mycosis fungoides).⁶⁹⁴

Confusion has arisen because of the retention of the term ‘parapsoriasis’ for two distinct conditions. In the United States, the term ‘parapsoriasis en plaque’ is usually used to refer to the entity that in the United Kingdom is called chronic superficial dermatitis.⁶⁹⁶ The term ‘parapsoriasis’ is also used for a condition with large plaques, which in 10–30% of cases progresses to a frank T-cell lymphoma of the skin.⁶⁹⁷ Studies have indicated monoclonal populations of T cells in 20% or more of cases of large plaque parapsoriasis.⁶⁹⁸

Brief mention is made of the three entities included in the original concept of parapsoriasis.

Pityriasis lichenoides shows features of both a chronic lymphocytic vasculitis and the lichenoid tissue reaction (see p. 261). It should no longer be considered as a variant of parapsoriasis.

Chronic superficial dermatitis (small plaque parapsoriasis) resembles a ‘mild eczema’, and it is therefore discussed in detail on p. 131 as part of the spongiotic tissue reaction. The spongiosis is often quite mild and in chronic lesions may be absent. In these circumstances, the epidermal acanthosis may assume psoriasiform proportions, hence its mention here also. It differs from psoriasis by the absence of dilated vessels in the papillary dermis and the absence of neutrophil exocytosis. Furthermore, chronic superficial dermatitis lacks a thin suprapapillary plate, and there is a paucity of mitoses in the keratinocytes (Fig. 4.17). Lymphocytes with a normal mature morphology are often found in the papillary dermis in chronic superficial dermatitis. This feature, combined with the regular acanthosis and focal parakeratosis, allows a diagnosis to be made in many cases with the scanning power of the light microscope. A dominant clonal pattern of T cells has been identified in some cases.^{699,700} Accordingly, it is often regarded as an early stage of cutaneous T-cell lymphoma. A study of 28 cases of small plaque parapsoriasis found 1 case that presented later with plaque-stage mycosis fungoides. The other 27 cases were non-progressive, although 3 of these cases had an oligoclonal pattern on molecular genetic studies.⁷⁰¹

Large plaque parapsoriasis, the third entity included originally as ‘parapsoriasis’, may also show features of psoriasiform epidermal

hyperplasia, although in atrophic and poikilodermatous lesions the epidermis is thin with loss of the rete ridge pattern. Basal vacuolar change and epidermotropism of lymphocytes are usually present. Large plaque parapsoriasis, a stage in the evolution of mycosis fungoides, is considered with other cutaneous lymphoid infiltrates on page 1175.

Finally, brief mention is made of the term ‘guttate parapsoriasis’. This term has been used in the past synonymously with both pityriasis lichenoides and chronic superficial dermatitis. It is best avoided.⁶⁹⁵

LICHEN SIMPLEX CHRONICUS

Lichen simplex chronicus (‘circumscribed neurodermatitis’) is an idiopathic disorder in which scaly, thickened plaques develop in response to persistent rubbing of pruritic sites.^{702,703} There is a predilection for the nape of the neck, the ulnar border of the forearms, the wrists, the pretibial region, the dorsa of the feet, and the perianal and genital region.^{703–705} Changes of lichen simplex chronicus have been reported to involve the palpebral conjunctiva.⁷⁰⁶ Atopic individuals are more prone than others to develop lichen simplex chronicus.⁷⁰⁷

Although not psoriasiform, mention is made of a recently described entity that clinically resembles lichen simplex chronicus or lichen amyloidosis but that has no histological similarities at all – **pretibial pruritic papular dermatitis**.⁷⁰⁸ The authors of that paper proposed that it was a response to chronic rubbing, possibly with other contributing factors, such as xerosis, contact with irritants, and emotional distress. The lesions were red to flesh colored, pruritic papules 3–8 mm in diameter. There was a cobblestone appearance in some later lesions. Lesions were unilateral in 33 of 44 cases and bilateral in 11 of 44. The histology showed mild compact orthokeratosis, flattening of the rete ridges, superficial dermal fibrosis, and a mild to moderate superficial and mid-dermal infiltrate of lymphocytes, histiocytes, and a few eosinophils. Stellate cells were present, probably a reflection of scratching. The published photomicrographs showed some resemblance to pigmented purpuric dermatosis, but there was no hemosiderin.⁷⁰⁸

Kinetic studies in lichen simplex chronicus have shown epidermal cell proliferation similar to that seen in psoriasis, although the transit time of the cells is not as fast.⁷⁰⁴ There is also an increase in mitochondrial enzymes in keratinocytes and in the number of melanocytes in the basal layer.⁷⁰⁹ Although these kinetic aspects are known, there is still no explanation for the pathogenesis of these plaques and the underlying pruritus; it is apparent, however, that self-induced trauma plays an important localizing role.⁷⁰⁴

Although beyond the scope of this book, an oral variant of lichen simplex chronicus has been described.⁷¹⁰ Also known as **benign alveolar ridge keratosis**, it is a common lesion that presents as a white papule or plaque on the keratinized gingiva of the maxillary or mandibular alveolar ridge. It is probably traumatic/frictional in origin.⁷¹⁰

The treatment of lichen simplex chronicus is often difficult, unless the scratching habit can be stopped. A sedative antihistamine may be useful. The usual treatment is a topical corticosteroid, but if thick plaques are present, potent corticosteroids under occlusion or triamcinolone injections may be needed.

Histopathology^{703,711}

A thick layer of compact orthokeratosis (resembling that seen on normal palms and soles) is present, overlying hypergranulosis. Focal zones of parakeratosis are sometimes interspersed with the orthokeratosis, but there is not the confluent parakeratosis of psoriasis.⁷⁰⁴ The epidermis shows psoriasiform hyperplasia with thicker rete ridges of less even length than in psoriasis. Epidermal thickness and volume are greater than in psoriasis.⁷⁰⁴ Minimal papillomatosis is sometimes present in a few areas. Focal excoriation is another change that may be seen in lichen simplex chronicus.

Figure 4.17 Chronic superficial dermatitis with psoriasiform hyperplasia, thick suprapapillary ‘plates’ of epidermis, and a mild, superficial lymphocytic infiltrate with some upward spread. (H&E)

Figure 4.18 Lichen simplex chronicus. The rete pegs are thinner than usual, but the vertical 'streaking' of collagen in the papillary dermis is well developed. (H&E)

There is marked thickening of the papillary dermis with bundles of collagen arranged in vertical streaks (**Fig. 4.18**).⁷¹¹ Scattered inflammatory cells and some fibroblasts are usually present in this region of the dermis. A finding occasionally described in lichen simplex chronicus is a type of giant cell first described by Montgomery in his text on dermatopathology and subsequently labeled the 'Montgomery giant cell'. He considered these cells to represent clumped endothelial cells and warned that they should not be confused with similar clumping of cells in mycosis fungoides or with Reed–Sternberg cells.⁷¹² Ackerman subsequently reported plump, stellate, and multinucleated fibroblasts, which he believed were not unique to lichen simplex chronicus but identifiable in other chronic processes associated with altered collagen.⁷¹³

Regional variations occur in lichen simplex chronicus. Epidermal hyperplasia is usually quite mild in lesions on the lip, whereas vertical-streaked collagen is unusual in lesions on the scalp or in mucocutaneous regions such as the vulva and perianal area.⁷¹¹

Changes such as those of lichen simplex chronicus may be superimposed on other dermatoses such as lichen planus (hypertrophic lichen planus), mycosis fungoides, actinic reticuloid, and eczematous dermatitides including atopic dermatitis.^{703,707} These changes are

particularly prominent in some solar keratoses of the hands or forearms.

The term 'prurigo nodularis' (see p. 788) is used for lesions with a nodular clinical appearance and prominent epidermal hyperplasia of pseudoepitheliomatous rather than psoriasiform type. Occasionally, lesions with overlapping clinical and histopathological features of both lichen simplex chronicus and prurigo nodularis are found. Prurigo nodularis is one condition in which the histological picture often lags behind the clinical appearance. The author has seen numerous cases, regarded by experienced dermatologists as prurigo nodularis, in which the histological picture was that of lichen simplex chronicus.

OTHER PSORIASIFORM DERMATOSES

This group of other psoriasiform dermatoses has been arbitrarily separated from the so-called 'major psoriasiform dermatoses' because of their inclusion in various other chapters, on the basis of their etiology or of other histopathological features. The comparative histopathological features of these various psoriasiform diseases are shown in **Table 4.4**.

SUBACUTE AND CHRONIC SPONGIOTIC DERMATITIDES

The various 'eczematous' dermatitides (allergic contact dermatitis, seborrheic dermatitis, nummular dermatitis, and atopic dermatitis) may show prominent psoriasiform epidermal hyperplasia in their subacute and chronic stages.

Histopathology

In subacute lesions, spongiosis is usually sufficiently obvious to allow a correct diagnosis. In some chronic lesions, particularly if activity has been dampened by treatment prior to the taking of a biopsy, the spongiosis may be quite mild or even absent. The features that distinguish chronic seborrheic dermatitis from psoriasis were discussed on page 89. In some cases of chronic atopic and nummular dermatitis, the epidermal hyperplasia is not as regular and as even as that seen in psoriasis, although this is by no means invariable. The presence of eosinophils and plasma cells in the superficial dermis would tend to exclude psoriasis. They may be found in any of the chronic spongiotic dermatitides that may simulate psoriasis histopathologically. The changes of lichen simplex chronicus may be superimposed on these chronic spongiotic dermatitides (**Fig. 4.19**).

ERYTHRODERMA

Erythroderma (exfoliative dermatitis) is a cutaneous reaction pattern characterized by erythema, edema, and scaling of all or most of the skin surface, often accompanied by pruritus (see p. 591). It may complicate a pre-existing dermatosis, follow the ingestion of a drug, or be associated with an internal cancer or with cutaneous T-cell lymphoma.

Histopathology

The findings are variable and often nonspecific. Psoriasiform hyperplasia, sometimes accompanied by mild spongiosis, may be present in cases of erythroderma not thought to be of psoriatic origin, whereas presumptive cases of erythrodermic psoriasis may show only nonspecific changes in the epidermis. The difficulties encountered in an attempted histopathological diagnosis of erythroderma are mentioned on page 591.

Table 4.4 Histopathological features of the various psoriasiform diseases	
Disease	Histopathological features
Psoriasis	Progressive psoriasiform epidermal hyperplasia, initially mild; mitoses in basal keratinocytes; dilated vessels in dermal papillae; parakeratosis, initially focal and containing neutrophils, later confluent with few neutrophils; thinning of the suprapapillary epidermis
Psoriasiform keratosis	Psoriasis-like, but often more parakeratosis (diffuse or focal)
Pustular psoriasis	Spongiform pustulation overshadows epidermal hyperplasia, except in lesions of some duration when both are present
Reiter's syndrome	Closely resembles pustular psoriasis; the overlying, thick scale crust often detaches during processing
Pityriasis rubra pilaris	Alternating orthokeratosis and parakeratosis, vertically and horizontally; follicular plugging with parafollicular (lipping) parakeratosis; mild to moderate epidermal hyperplasia; no neutrophil exocytosis
Parapsoriasis	Variable epidermal hyperplasia; the superficial perivascular or band-like infiltrate involves the papillary dermis ('spills upwards'); some exocytosis/epidermotropism; probably represents early cutaneous lymphoma
Lichen simplex chronicus	Conspicuous psoriasiform hyperplasia, sometimes irregular; prominent granular layer with patchy parakeratosis; thick suprapapillary epidermal plates; thick collagen in vertical streaks in papillary dermis; variable inflammatory infiltrate and plump fibroblasts
Chronic spongiotic dermatitides	Progressive psoriasiform hyperplasia, usually with diminishing spongiosis eventually merging with picture of lichen simplex chronicus; chronic nummular lesions 'untidy' with mild exocytosis; eosinophils may be present in nummular and allergic contact lesions; chronic seborrheic dermatitis may mimic psoriasis but no neutrophils, less hyperplasia, and sometimes perifollicular parakeratosis
Erythroderma	Variable psoriasiform hyperplasia; usually focal spongiosis; no distinguishing features
Mycosis fungoides	Epidermotropism; papillary dermal infiltrate of lymphocytes with variable cytological atypia
Chronic candidosis and dermatophytoses	Psoriasiform hyperplasia not as regular or as marked as in psoriasis; spongiform pustules or neutrophils in parakeratotic scale; fungal elements may be sparse in candidosis
ILVEN	Papillated psoriasiform hyperplasia with foci of parakeratosis overlying hypogranulosis; often focal mild spongiosis; may have alternating orthokeratosis and parakeratosis in a horizontal direction
Norwegian scabies	Marked orthokeratosis and scale crust; numerous mites, larvae, and ova in the keratinous layer
Bowen's disease (psoriasiform type)	Full-thickness atypia of keratinocytes but basal layer sometimes spared; cells sometimes pale staining
Clear cell acanthoma	Pallor of keratinocytes but no atypia; abundant glycogen; some exocytosis of inflammatory cells
Lamellar ichthyosis	Mild psoriasiform hyperplasia with a thick compact or laminated orthokeratin layer overlying a prominent granular layer
Pityriasis rosea (herald patch)	Mild psoriasiform hyperplasia; spongiosis and exocytosis of lymphocytes leading to 'mini-Pautrier simulants'; focal parakeratosis
Pellagra, acrodermatitis enteropathica, and glucagonoma syndrome	Mild to moderate psoriasiform hyperplasia; upper epidermis shows pallor and ballooning progressing sometimes to necrosis, vesiculation, or pustulation (not in pellagra); confluent parakeratosis overlying these changes; many cases of pellagra show mild, even nonspecific, changes
Secondary syphilis	Superficial and deep dermal infiltrate that often includes plasma cells; may have lichenoid changes or granuloma formation in late stages

Figure 4.19 Chronic allergic contact dermatitis with psoriasiform hyperplasia of the epidermis and small foci of spongiosis. (H&E)

MYCOSIS FUNGOIDES

Mycosis fungoides is a cutaneous T-cell lymphoma with three clinical stages – patch, plaque, and tumor. Its varied clinical features are discussed on page 973.

Histopathology

Psoriasiform hyperplasia of the epidermis is not uncommon in mycosis fungoides. It is usually of mild to moderate proportions. The presence of epidermotropism and variable cytological atypia of the lymphocytic infiltrate are features that distinguish this condition from other psoriasiform dermatoses (Fig. 4.20).

CHRONIC CANDIDOSIS AND DERMATOPHYTOSES

Psoriasiform epidermal hyperplasia may be present in lesions of chronic candidosis (see p. 691) and, rarely, in chronic dermatophyte infections, most notably in tinea imbricata.

Histopathology

The rete ridges are not unusually long in the psoriasiform hyperplasia of chronic candidosis. There are usually a few neutrophils and some

Figure 4.20 Mycosis fungoides. There is psoriasiform hyperplasia of the epidermis and conspicuous epidermotropism of lymphocytes. (H&E)

serum in the overlying parakeratotic scale. Fungal elements, in the form of yeasts and pseudohyphae, may be sparse and difficult to find with the PAS stain. They are often more readily seen in methenamine silver preparations.

Hyphae and spores are usually abundant in the thick stratum corneum in tinea imbricata.

INFLAMMATORY LINEAR VERRUCOUS EPIDERMAL NEVUS

The acronym ILVEN is often used in place of the more cumbersome inflammatory linear verrucous epidermal nevus. This condition is a variant of epidermal nevus that usually presents as a pruritic, linear eruption on the lower extremities (see p. 786). It must be distinguished from linear psoriasis.

Histopathology

The characteristic feature is the presence of alternating zones of orthokeratosis and parakeratosis in a horizontal direction, overlying a psoriasiform epidermis (**Fig. 4.21**). The zones of parakeratosis overlie areas of agranulosis. Focal mild spongiosis is often present as well.

NORWEGIAN SCABIES

Norwegian (crusted) scabies is a rare form of scabies that is usually found in the mentally and physically debilitated; it also occurs in immunosuppressed individuals (see p. 772). There are widespread crusted and secondarily infected hyperkeratotic lesions.

Histopathology

Overlying the psoriasiform epidermis, there is a very thick layer of orthokeratosis and parakeratosis containing numerous scabies mites at all stages of development. The appearances are characteristic (**Fig. 4.22**).

BOWEN'S DISEASE

There is a variant of Bowen's disease in which the epidermis shows psoriasiform hyperplasia (see p. 801). It has no distinguishing clinical features.

Figure 4.21 Inflammatory linear verrucous epidermal nevus (ILVEN). (A) Note the psoriasiform epidermal hyperplasia. (B) There are broad zones of parakeratosis alternating with orthokeratosis. The granular layer is absent beneath the parakeratotic zones. (H&E)

Figure 4.22 Norwegian scabies. The thick stratum corneum that overlies the psoriasiform epidermis contains a number of scabies mites. (H&E)

Figure 4.23 Bowen's disease. There is psoriasiform epidermal hyperplasia and full-thickness atypia. (H&E)

Histopathology

There is psoriasiform hyperplasia with a thick suprapapillary plate. Atypical keratinocytes usually involve the full thickness of the epidermis; sometimes there is sparing of the basal layer and the acrosyringium (Fig. 4.23). Mitoses and dyskeratotic cells are usually present. Uncommonly, the psoriasiform variant of Bowen's disease is composed of pale pagetoid cells.

CLEAR CELL ACANTHOMA

The clear (pale) cell acanthoma presents as a papulonodular lesion, usually on the lower parts of the legs (see p. 794).

Histopathology

The characteristic feature is the presence of a well-demarcated area of psoriasiform epidermal hyperplasia in which the cells have palely staining cytoplasm. Exocytosis of inflammatory cells may also be present. The pale keratinocytes contain abundant glycogen.

LAMELLAR ICHTHYOSIS

This is a rare, severe, autosomal recessive form of ichthyosis (see p. 286). It is usually manifest at birth.

Histopathology

There is prominent orthokeratosis and focal parakeratosis overlying a normal or thickened granular layer. Psoriasiform epidermal hyperplasia is sometimes present, although usually the epidermis shows only moderate acanthosis. Psoriasiform hyperplasia is also found in some cases of ichthyosis congenita (see p. 285) and Netherton's syndrome (see p. 288). Biopsies of the ichthyosis linearis circumflexa that is a component of Netherton's syndrome may be misdiagnosed as congenital psoriasis (Fig. 4.24).

PITYRIASIS ROSEA

The 'herald patch' of pityriasis rosea may show the psoriasiform tissue reaction (see p. 112).

Figure 4.24 Ichthyosis linearis circumflexa. Distinguishing this lesion from psoriasis is sometimes difficult. (H&E)

Histopathology

There is usually acanthosis and only mild psoriasiform hyperplasia. Small 'Pautrier simulants' (pityriasiform spongiosis), composed of inflammatory cells in a spongiotic focus, are often seen. There is usually focal parakeratosis overlying the epidermis.

PELLAGRA

Pellagra is caused by an inadequate amount of niacin (nicotinic acid) in the tissues. Skin lesions include a scaly erythematous rash in sun-exposed areas, sometimes with blistering, followed by hyperpigmentation and epithelial desquamation (see p. 561).

Histopathology

The findings are not usually diagnostic. Sometimes there is psoriasiform acanthosis with pallor of the upper epidermis and overlying orthokeratosis and focal parakeratosis. The psoriasiform acanthosis is more common in mixed nutritional deficiency states.

ACRODERMATITIS ENTEROPATHICA

Acrodermatitis enteropathica, a rare disorder resulting from zinc deficiency, presents with periorificial and acral lesions that may be eczematous, vesiculobullous, pustular, or an admixture of these patterns (see p. 567).

Histopathology

In established lesions, there is confluent parakeratosis overlying psoriasiform epidermal hyperplasia. The upper layers of the epidermis show a characteristic pallor, and sometimes there is focal necrosis or subcorneal clefting. The epidermal pallor disappears in late lesions.

GLUCAGONOMA SYNDROME

Necrolytic migratory erythema is the term used for the cutaneous lesions of the glucagonoma syndrome. This syndrome in most cases is a manifestation of a glucagon-secreting islet cell tumor of the pancreas (see p. 569).

Figure 4.25 Glucagonoma syndrome. There is very little vacuolation of keratinocytes, although it was present in another biopsy from this patient. (H&E)

Histopathology

The changes may resemble those seen in acrodermatitis enteropathica with psoriasiform hyperplasia, upper epidermal pallor, and overlying confluent parakeratosis. At other times, there is focal or confluent necrosis of the upper epidermis with a preceding phase of pale, vacuolated keratinocytes. Subcorneal or intraepidermal clefting and pustulation may develop. Psoriasiform epidermal hyperplasia of any significant degree is present in only a minority of cases ([Fig. 4.25](#)).

SECONDARY SYPHILIS

The great imitator, syphilis, can sometimes present lesions, in the secondary phase, with a psoriasiform pattern (see p. 675).

Figure 4.26 Late secondary syphilis. The epidermal hyperplasia is less regular than is usual in psoriasiform hyperplasia. There are focal lichenoid changes. (H&E)

Histopathology

It should be stressed that there is considerable variation in the histopathological appearances of secondary syphilis. Psoriasiform hyperplasia is more often seen in late lesions of secondary syphilis. A lichenoid tissue reaction may also be present, and this combination of tissue reactions is very suggestive of syphilis, particularly if the infiltrate in the dermis forms in both the superficial and deep parts ([Fig. 4.26](#)). Plasma cells are commonly present, but they are not invariable.

INTRODUCTION

The spongiotic tissue reaction is characterized by the presence of intraepidermal and intercellular edema (spongiosis) (Fig. 5.1). It is recognized by the widened intercellular spaces between keratinocytes, with elongation of the intercellular bridges (Fig. 5.2).¹ The foci of spongiosis may vary from microscopic in size to grossly identifiable vesicles and even bullae. Mild spongiosis is well seen in semi-thin sections.² Inflammatory cells, usually lymphocytes but sometimes eosinophils or even neutrophils, are also present.¹

The spongiotic tissue reaction is a histopathological concept and not a clinical one, although several of the many diseases with this tissue reaction have been included, in the past, in the category of 'eczemas'. This term (derived from Greek elements that mean 'boiling over') has fallen into some disrepute in recent years because it lacks precision.³⁻⁵ The 'eczemas' all show epidermal spongiosis at some stage of their evolution, even though this has been disputed for atopic eczema. Clinically, the various spongiotic disorders may present with weeping,

Figure 5.1 The spongiotic reaction pattern. There is mild intracellular edema leading to pallor of the keratinocytes, in addition to the intercellular edema. (H&E)

Figure 5.2 The spongiotic reaction pattern. Note the elongation of the intercellular bridges resulting from the intercellular edema. Occasional eosinophils are present within the epidermis. (H&E)

crusted patches and plaques, as in the so-called 'eczemas', or as erythematous papules, papulovesicles, and even vesiculobullous lesions. Resolving lesions and those of some duration may show a characteristic collarette of scale.

The mechanism involved in the collection of the intercellular fluid is controversial. It is generally accepted that the fluid comes from the dermis and, in turn, from blood vessels in the upper dermis. Various immunological reactions are involved in some of the diseases discussed in this chapter, but in others the etiology of this fluid extravasation from vessels remains to be elucidated. The controversy also involves the mechanism by which the dermal edema fluid enters the epidermis.^{6,7} One concept is that an osmotic gradient develops toward the epidermis, drawing fluid into it.⁶ The opposing view suggests that hydrostatic pressure leads to the epidermal elimination of dermal edema.⁸ The latter explanation does not satisfactorily explain the absence of spongiosis in pronounced urticarial reactions. Perhaps both mechanisms are involved to a varying degree. The spongiotic tissue reaction is a dynamic process.⁹ Vesicles come and go, and they can be situated at different levels in the epidermis.⁹ Parakeratosis forms above areas of spongiosis, probably as a result of an acceleration in the movement of keratinocytes toward the surface, although disordered maturation may contribute.¹⁰ Small droplets of plasma may accumulate in the mounds of parakeratosis, contributing to the appearance of the collarettes of scale mentioned previously.¹⁰

Simulants of the spongiotic tissue reaction

There are several categories of disease in which casual histological examination may show a simulation of the spongiotic reaction pattern: they are excluded from consideration here.¹ Diseases that present a lichenoid reaction pattern with obscurement of the dermoepidermal interface (e.g., pityriasis lichenoides, erythema multiforme, and fixed drug eruption) or prominent vacuolar change (variants of lupus erythematosus) may show some spongiosis above the basal layer. They are not included among the diseases considered in this chapter.

Certain viral exanthems and morbilliform drug eruptions show mild epidermal spongiosis, but it is usually limited to the basal layer of the epidermis. Other viral diseases, such as herpes simplex and herpes zoster, show ballooning degeneration of keratinocytes with secondary acantholysis. Some spongiosis is invariably present, but it is overshadowed by the other changes. Primary acantholytic disorders leading to vesiculation are also excluded. Mild spongiosis is seen overlying the dermal papillae in early lesions of psoriasis, but again this disease is not usually regarded as a spongiotic disorder.

The accumulation of acid mucopolysaccharides in the follicular infundibulum in follicular mucinosis may simulate spongiosis. Stains for mucin, such as the colloidal iron stain, will confirm the diagnosis, if any doubt exists.

Finally, the Pautrier microabscesses of mycosis fungoides may be simulated by the collections of mononuclear cells that sometimes accumulate in spongiotic dermatitis (Fig. 5.3). In spongiotic dermatitis, the cellular collections often assume a vase-like shape, with the lips of the vase situated at the interface between the granular and cornified layers.¹¹ The intraepidermal collections of mononuclear cells express CD1a, S100 protein, CD36, and CD68. They lack CD14, which is found on mature Langerhans cells. Their phenotype suggests derivation from circulating monocytes and differentiation into mature Langerhans cells.¹²

Patterns of spongiosis

Five special patterns of spongiosis can be distinguished morphologically from the more usual type. These are *neutrophilic spongiosis*, in which there are numerous neutrophils associated with epidermal spongiosis; *eosinophilic spongiosis*, characterized by the presence of

Figure 5.3 A Pautrier simulant in a spongiotic dermatitis. There were numerous Langerhans cells within the vesicle. (H&E)

Figure 5.4 Neutrophilic spongiosis characterized by the presence of neutrophils within spongiotic vesicles. (H&E)

numerous eosinophils within the spongiotic foci; *miliarial spongiosis*, in which the edema is centered on the acrosyringium; *follicular spongiosis*, in which there is involvement of the follicular infundibulum; and *pityriasiform spongiosis*, in which there are spongiotic microvesicles containing lymphocytes $\pm$ Langerhans cells. Sometimes serial sections are required before it is appreciated that the spongiosis is related to the acrosyringium or acrotrichium. Diseases in these special categories are discussed first, followed by a description of the more usual type of spongiotic disorders. The histopathological features of the pityriasiform and other spongiotic diseases are included in [Table 5.1](#).

NEUTROPHILIC SPONGIOSIS

Neutrophilic spongiosis is characterized by the presence of neutrophils within spongiotic foci in the epidermis ([Fig. 5.4](#)). The term spongiform pustular dermatitis can be used for a severe form of neutrophilic spongiosis in which pustules can be seen clinically and histologically. Subcorneal pustules are excluded from this category. Ackerman states that neutrophils are absent in 'authentic' spongiotic dermatitides,¹³ but a case can be made for including the following conditions in this histological pattern:

- Pustular psoriasis
- Prurigo pigmentosa
- Reiter's syndrome
- Pemphigus foliaceus
- IgA pemphigus
- Herpetiform pemphigus
- Infantile acropustulosis
- Acute generalized exanthematous pustulosis
- Palmoplantar pustulosis
- Staphylococcal toxic shock syndrome
- Neisserial infections
- Dermatophytoses
- Candidosis
- Beetle (*Paederus*) dermatitis
- Pustular contact dermatitis
- Glucagonoma syndrome
- Amicrobial pustulosis associated with autoimmune diseases
- Erosive pustular dermatosis of the legs

- Amicrobial pustulosis of the folds
- Periodic fever syndromes.

Reiter's syndrome (see p. 92) shares histological features with pustular psoriasis. It is not considered further. If spongiosis occurs in pemphigus foliaceus, it is usually of eosinophilic type. Neutrophilic spongiosis has been reported in a case that evolved into an atypical pemphigus phenotype.¹⁴ In infantile acropustulosis (see p. 144), there are variable numbers of eosinophils admixed with the neutrophils. In palmoplantar pustulosis (see p. 147), large vesicles are the dominant feature, with only some neutrophilic spongiosis at the edges. This tissue reaction can also be seen in the staphylococcal toxic shock syndrome (see p. 640) and in infections with *Neisseria* species (see p. 648). Pustular contact dermatitis is considered later in this chapter (see p. 118). The glucagonoma syndrome is considered in Chapter 18. Amicrobial pustulosis associated with autoimmune diseases and herpetiform pemphigus are discussed in Chapter 6. Erosive pustular dermatosis of the legs is discussed in Chapter 6. Amicrobial pustulosis of the folds and the periodic fever syndromes are included in Chapter 8.

PUSTULAR PSORIASIS

In both pustular psoriasis (see p. 91) and Reiter's syndrome (see p. 92) there is characteristic spongiform pustulation.

PRURIGO PIGMENTOSA

Prurigo pigmentosa is an inflammatory dermatosis characterized by the sudden onset of pruritic erythematous papules, usually involving the trunk and neck, that coalesce to form reticulated, mottled patches.¹⁵ Vesicles and bullae are uncommon. Because it resolves leaving mottled or reticulate hyperpigmentation, it is discussed further in Chapter 10.

Histopathology

In the established papular phase, there is variable spongiosis, acanthosis, exocytosis of lymphocytes, and a few neutrophils with isolated apoptotic keratinocytes. In early stages of the disease, there is neutrophilic spongiosis with some apoptotic keratinocytes at all levels of the epidermis. There is a mild superficial perivascular infiltrate of lymphocytes and neutrophils and a few eosinophils in the earlier

Table 5.1 Histopathological features of the spongiotic diseases (excluding eosinophilic, miliarial, and follicular variants)	
Disease	Histopathological features
Irritant contact dermatitis	Superficial ballooning, necrosis, and neutrophils; mild irritants produce spongiotic dermatitis mimicking allergic contact dermatitis, although superficial apoptotic keratinocytes may also be present
Allergic contact dermatitis	Variable spongiosis and vesiculation at different horizontal and vertical levels, with an 'ordered' pattern; mild exocytosis; progressive psoriasiform hyperplasia with chronicity; usually eosinophils in superficial dermal infiltrate; superficial dermal edema
Protein contact dermatitis	No distinguishing features recorded; an urticarial component may be present
Nummular dermatitis	May mimic allergic contact dermatitis but usually more 'untidy'. Neutrophils may be in dermal infiltrate and even the epidermis; the psoriasiform hyperplasia in chronic cases may show variable thickening of adjacent rete pegs
Seborrheic dermatitis	Variable spongiosis and psoriasiform hyperplasia depending on activity and chronicity; scale crust and spongiosis may localize to follicular ostia
Atopic dermatitis	Mimics other spongiotic diseases with variable spongiosis (usually quite mild) and psoriasiform hyperplasia; subtle features include prominence of vessels in the papillary dermis, increased epidermal volume without necessarily producing psoriasiform folding; eosinophil major basic protein present, sometimes disproportionate to eosinophils
Pompholyx	Vesiculation with peripheral displacement of acrosyringia; process usually more sharply defined than allergic contact dermatitis of palms and soles; some evolve into picture of pustulosis palmaris with neutrophils (important to exclude fungi in these cases with PAS stain)
Stasis dermatitis	Mild spongiosis only; proliferation of superficial dermal vessels; extravasation of erythrocytes; abundant hemosiderin
Autoeczematization	Variable spongiosis; edema of papillary dermis and activated lymphocytes often present
Pityriasis rosea	Pityriasiform spongiosis with focal parakeratosis; lymphocyte exocytosis; sometimes erythrocyte extravasation in papillary dermis; 'herald patch' is more psoriasiform
Papular acrodermatitis of childhood	Three tissue reaction patterns (lichenoid, spongiotic, and lymphocytic vasculitis) often present; small spongiotic vesicles resembling pityriasis rosea may be present
Spongiotic drug reactions	Spongiosis with conspicuous exocytosis of lymphocytes relative to the amount of spongiosis; rare apoptotic keratinocytes; eosinophils, plasma cells, and activated lymphocytes may be in superficial dermal infiltrate; may show mid-dermal spillover; sometimes superficial dermal edema
Chronic superficial dermatitis	Only mild spongiosis and focal parakeratosis with variable psoriasiform hyperplasia; superficial perivascular infiltrate with characteristic upward extension and mild exocytosis
Light reactions	Variable, usually mild spongiosis; superficial and deep perivascular dermal inflammation; a deep infiltrate is not invariable in lesions of short duration; subepidermal edema in some cases of polymorphic light eruption; stellate fibroblasts, vertical collagen streaking, variable psoriasiform hyperplasia and some atypical lymphocytes with exocytosis in actinic reticuloid; scattered 'sunburn cells' in phototoxic lesions (sometimes with only mild other changes); deeply extending, straight, basophilic (elastotic) fibers in lesions of long duration
Dermatophytoses	Neutrophils in stratum corneum, or compact orthokeratosis or 'sandwich sign' should alert observer to perform a PAS stain; spongiotic vesicles may form on palms and soles
Arthropod bites	Spongiotic vesicles containing variable numbers of eosinophils; superficial and deep dermal inflammation with interstitial eosinophils
Grover's disease	Spongiosis with focal acantholysis in the spongiotic variant; untidy superficial dermal inflammation
Toxic erythema of pregnancy	Spongiosis mild and inconstant; variable papillary dermal edema; tight superficial perivascular infiltrate sometimes extending to mid dermis; interstitial eosinophils in some cases
Erythema annulare centrifugum	Pityriasiform spongiosis at periphery of lesion; mild perivascular cuffing with lymphocytes; late lesions lack spongiosis
Pigmented purpuric dermatoses	Spongiosis mild and inconstant; lymphocytic vasculitis with variably dense infiltrate in the papillary dermis; hemosiderin in the upper dermis
Pityriasis alba	Clinical diagnosis; mild focal spongiosis with minimal parakeratosis
Erythroderma	Mild spongiosis; variable psoriasiform hyperplasia; appearances depend on underlying disease; a difficult diagnosis without clinical history
Mycosis fungoides	Mild spongiosis, variable epidermal hyperplasia and epidermal mucinosis; epidermotropism, often with Pautrier microabscesses; variable cytological atypia of lymphocytes that extend upward into the papillary dermis

stages. A Korean study reported perivascular neutrophilic infiltrates with some papillary dermal neutrophils in early lesions and also neutrophilic spongiosis in fully developed lesions.¹⁶ Pigment incontinence is a conspicuous feature of late lesions.

IgA PEMPHIGUS

IgA pemphigus is a vesiculobullous disease (see p. 143) with a variable expression, accounting for the many titles applied to this condition in the past. There are subcorneal and/or intraepidermal pustules with

usually only mild acantholysis. IgA is deposited in the epidermis in an intercellular position.

ACUTE GENERALIZED EXANTHEMATOUS PUSTULOSIS

Acute generalized exanthematous pustulosis is a rapidly evolving pustular eruption (see p. 145), usually associated with the ingestion of drugs, particularly antibiotics. There are subcorneal and superficial

intraepidermal pustules. Subepidermal pustules are sometimes present with prominent neutrophil exocytosis and neutrophilic spongiosis.

DERMATOPHYTOSES AND CANDIDOSIS

Neutrophilic spongiosis can be found with dermatophyte infection and also with the yeast *Candida*. The presence of neutrophils in the epidermis and/or overlying stratum corneum should always lead to the performance of a PAS stain.

BEETLE (*PAEDERUS*) DERMATITIS

Vesicular dermatitis, characterized by areas of neutrophilic spongiosis, results from contact with various beetles (order Coleoptera).^{17–19} Bullae and small pustules may even result. The term *Paederus* dermatitis is used for the reaction produced by the genus *Paederus*, of which there are several hundred species capable of producing a form of acute irritant contact dermatitis.¹⁸ The irritant substance is pederin, a highly toxic alkaloid produced by members of this genus. Localized erythema occurs first, followed by blisters after 2–4 days, associated with increasing pain.¹⁷ Lesions are commonly linear due to crushing of the beetle on the skin, followed by its wiping off the skin. The delay in the appearance of the lesions may lead to lack of recognition of the causal event.

Histopathology

Early lesions show neutrophilic spongiosis leading to vesiculation and eventual reticular necrosis of the epidermis. This is followed by confluent epidermal necrosis, usually with a surviving layer of suprabasal cells. Scattered acantholytic cells may be present. The large number of intraepidermal neutrophils, combined with areas of confluent necrosis and reticular degeneration, are characteristic. Older lesions show irregular acanthosis and pallor of superficial keratinocytes, with overlying parakeratotic scale containing a neutrophil exudate.¹⁷

A similar spongiotic and vesicular dermatitis, with the addition of vasculitis, has been produced by the hide beetle, *Dermestes peruvianus*.²⁰

EOSINOPHILIC SPONGIOSIS

Eosinophilic spongiosis is a histological reaction pattern characterized by the presence of epidermal spongiosis associated with the exocytosis of eosinophils into the spongiotic foci.²¹ Microabscesses, containing predominantly eosinophils, are formed.

Eosinophilic spongiosis is found in a heterogeneous group of dermatoses,²² most of which are considered elsewhere. It can be seen in the following conditions:

- Pemphigus (precursor lesions)
- Pemphigus vegetans
- Herpetiform pemphigus
- Bullous pemphigoid
- Cicatricial pemphigoid
- Herpes gestationis
- Idiopathic eosinophilic spongiosis
- Eosinophilic, polymorphic, and pruritic eruption
- Allergic contact dermatitis
- Atopic dermatitis
- Arthropod bites
- Eosinophilic folliculitis (Ofuji's disease)
- Incontinentia pigmenti (first stage)

Figure 5.5 Eosinophilic spongiosis as a precursor of pemphigus foliaceus. (H&E)

- Drug reactions
- 'Id' reactions
- Still's disease²³
- Vulvar lichen sclerosis (rare)
- Wells' syndrome.

PEMPHIGUS (PRECURSOR LESIONS)

Eosinophilic spongiosis may occur in the preacantholytic stage of both pemphigus foliaceus and pemphigus vulgaris.^{21,24–26} In these early stages, direct immunofluorescence demonstrates the presence of IgG in the intercellular areas of the epidermis.²⁴ In patients whose disease evolves into pemphigus foliaceus, the initial clinical presentation may resemble dermatitis herpetiformis.^{25,27} Some of these cases have been reported in the literature as herpetiform pemphigus.^{28,29}

Histopathology

The pattern is that described for eosinophilic spongiosis (Fig. 5.5). Acantholysis and transitional forms between eosinophilic spongiosis and the usual histological findings in pemphigus may be present.

PEMPHIGUS VEGETANS

Eosinophils are often prominent within the vesicles of pemphigus vegetans. Acantholysis, epidermal hyperplasia, and the absence of spongiosis adjacent to the suprabasal vesicles usually allow the diagnosis of pemphigus vegetans to be made.

BULLOUS PEMPFIGOID

Eosinophilic spongiosis is an uncommon finding in the urticarial stage of bullous pemphigoid and in erythematous patches adjacent to characteristic bullae in later stages of the disease.³⁰ In one case, the eosinophilic spongiosis preceded the diagnosis of bullous pemphigoid by 13 years.³¹ There is usually a prominent dermal infiltrate of eosinophils, and IgG is demonstrable along the basement membrane zone.

IDIOPATHIC EOSINOPHILIC SPONGIOSIS

Several cases have been recorded in which a localized, recurrent bullous eruption has been associated with the histological appearance

of eosinophilic spongiosis.³² Polycythemia rubra vera was present in one case.³³

EOSINOPHILIC, POLYMORPHIC, AND PRURITIC ERUPTION

Eosinophilic, polymorphic, and pruritic eruption, associated with the use of radiotherapy, particularly for carcinoma of the breast, has not been well characterized.^{34–36} Similar cases have been reported in the past, often without histological confirmation, under several different designations, including erythema multiforme and bullous pemphigoid after radiation therapy.³⁴ The rash is widespread, polymorphic, and intensely pruritic, commencing during radiotherapy and lasting several weeks or months. The lesions are usually erythematous papules, measuring 3–10 mm in diameter. Wheals, vesicles, and tense subepidermal blisters are less common. The eruption often develops in areas well away from their radiated area.³⁷

Histopathology

The variable histological appearances reflect the polymorphic nature of the rash. There is usually spongiosis with focal spongiotic vesiculation. There may be some acanthosis in lesions of longer duration and secondary changes of rubbing and scratching. The dermal infiltrate is usually superficial and deep and of moderate severity. Extension into the subcutis sometimes occurs. Eosinophils are always present. There is usually some eosinophilic spongiosis; an eosinophilic panniculitis is much less common. If bullae are present, they usually resemble bullous pemphigoid. There are no features of erythema multiforme, despite earlier publications attributing this condition to erythema multiforme.

ALLERGIC CONTACT DERMATITIS

Eosinophilic spongiosis may be seen in allergic contact dermatitis (see p. 116).

ARTHROPOD BITES

Eosinophilic spongiosis is occasionally seen in the reaction to the bite of certain arthropods, particularly the scabies mite (see p. 772).

EOSINOPHILIC FOLLICULITIS

In eosinophilic folliculitis (Ofuji's disease; see p. 463), the eosinophilic spongiosis involves the follicular infundibulum; sometimes the immediately adjacent epidermis is also involved.

INCONTINENTIA PIGMENTI

In the first stage of incontinentia pigmenti (see p. 341), there is prominent exocytosis of eosinophils into the epidermis and foci of eosinophilic spongiosis (Fig. 5.6). Occasional dyskeratotic keratinocytes may also be present.

VULVAR LICHEN SCLEROSUS

Several papers have described examples of vulvar lichen sclerosis (see p. 361) displaying the changes of eosinophilic spongiosis.^{38,39} When found together with dermal eosinophilic infiltrates, excoriations, and lymphocyte exocytosis, eosinophilic spongiosis may predict a poor symptomatic response to therapy of this disease.⁴⁰

Figure 5.6 Eosinophilic spongiosis in the first stage of incontinentia pigmenti. (H&E)

MILIARIAL SPONGIOSIS

Miliarial spongiosis is characterized by intraepidermal edema centered on the acrosyringium. It is characteristic of the various clinical forms of miliaria.

MILIARIA

The miliarias are a clinically heterogeneous group of diseases that occur when the free flow of eccrine sweat to the skin surface is impeded. Three variants of miliaria have been defined according to the depth at which this sweat duct obstruction occurs.

Miliaria crystallina (miliaria alba), which results from superficial obstruction in the stratum corneum, is characterized by asymptomatic, clear, 1- to 2-mm vesicles that rupture easily with gentle pressure.⁴¹ Congenital onset is exceedingly rare.^{42,43} Onset in the first week of life is not uncommon.⁴⁴ It has also been reported in adult patients in an intensive care setting.⁴⁵ It may have been caused by drugs producing enhanced α -adrenergic stimulation of sweat gland myoepithelium.⁴⁵ Isotretinoin can also cause miliaria crystallina.⁴⁵ It is a self-limited

condition that resolves without complications over a period of several days.

Miliaria rubra (prickly heat) consists of small, discrete, erythematous papulovesicles with a predilection for the clothed areas of the body.⁴⁶ The lesions are often pruritic. In severe cases, with recurrent crops of lesions, anhidrosis may result.⁴⁷ Occasionally, pustular lesions (*miliaria pustulosa*) may coexist. Both miliaria rubra and pustular miliaria rubra have been reported in infants and children with type I pseudohypoaldosteronism.^{48–50} Miliaria rubra can also occur in Morvan's syndrome, a form of generalized myokymia (OMIM 160120).⁵¹

Miliaria profunda refers to the development of flesh-colored papules resembling gooseflesh, associated with obstruction of the sweat duct near the dermoepidermal junction.^{52,53} It usually follows severe miliaria rubra and is associated with anhidrosis. A case has been reported in which large white plaques with an erythematous border were present.⁵⁴ The lesions expanded centrifugally until they were several centimeters or more in diameter. They were localized to sites at which occlusive tape had been applied. This variant has been called giant centrifugal miliaria profunda.⁵⁴

Although it has been presumed since the 19th century that obstruction of the eccrine duct is involved in the pathogenesis of the miliarias, the nature of this obstruction and its etiology have been the subject of much debate.⁵² The first demonstrable histological change is the accumulation of PAS-positive, diastase-resistant material in the distal pore,⁵² although this has not always been found.⁵⁵ This material has been designated 'extracellular polysaccharide substance' (EPS).⁵⁶ It is likely that there is an earlier stage of obstruction, which cannot be demonstrated in tissue sections. After several days, a keratin plug forms as part of the repair process, leading to further obstruction of the duct, often at a deeper level. Various factors may contribute to the initial duct obstruction,^{57,58} including changes in the horny layer related to excess sweating, the presence of sodium chloride in more than isotonic concentration,⁵⁵ and lipid depletion. In many cases, there is an increase in the number of resident aerobic bacteria, particularly cocci.^{52,59–61} Certain strains of *Staphylococcus epidermidis* produce the PAS-positive material known as EPS (mentioned previously), and these organisms may play a central role in the pathogenesis of miliaria.⁵⁶ Miliaria have also developed at the site of previous radiotherapy; there was associated keratotic plugging of the eccrine orifices.⁶²

Histopathology

In *miliaria crystallina*, there is a vesicle within or directly beneath the stratum corneum. There is often a thin, orthokeratotic layer forming the roof of the vesicle and a basket-weave layer of keratin in the base. A PAS-positive plug may be seen in the distal sweat pore.

Miliaria rubra is characterized by variable spongiosis and spongiotic vesiculation related to the epidermal sweat duct unit and the adjacent epidermis (Fig. 5.7). There is a small number of lymphocytes in the areas of spongiosis. An orthokeratotic or parakeratotic plug may overlie the spongiosis.⁴⁶ Sometimes there is edema in the papillary dermis adjacent to the point of entry of the eccrine duct into the epidermis. A mild lymphocytic infiltrate is usually present in this region. If the edema is pronounced, leading to subepidermal vesiculation, then *miliaria profunda* is said to be present. Biopsies of two infants with giant centrifugal miliaria profunda featured hyperplasia of eccrine sweat ducts, ortho- and parakeratotic plugging, and granulomatous infiltrates around the straight intradermal portions of these ducts.⁶³ Miliaria pustulosa is characterized by neutrophils beneath the stratum corneum and/or in the epidermal sweat duct (Fig. 5.8).

Less commonly, there is only slight spongiosis in the region of the acrosyringium in miliaria rubra associated with dilatation of the terminal eccrine duct.⁴⁶ It should be remembered that not all eccrine ducts are involved.

Figure 5.7 Miliaria rubra. (A) The spongiosis is related to the acrosyringium. (B) There is edema in the wall of the eccrine duct as it enters the epidermis and also in the adjacent papillary dermis. (H&E)

Figure 5.8 Miliaria pustulosa. The pustule often extends well beyond the limits of the involved acrosyringium, making the diagnosis difficult. (H&E)

The secretory acini show few changes in the miliarias.⁴⁶ They may be mildly dilated. Often, there is slight edema of the connective tissue between the secretory units. Lymphocytes are not usually present, unless there is a prominent inflammatory cell infiltrate elsewhere in the dermis.

FOLLICULAR SPONGIOSIS

Follicular spongiosis refers to the presence of intercellular edema in the follicular infundibulum (Fig. 5.9). It occurs in a limited number of circumstances:

- Infundibulofolliculitis
- Atopic dermatitis (follicular lesions)
- Apocrine miliaria
- Eosinophilic folliculitis.

INFUNDIBULOFOLLICULITIS

Infundibulofolliculitis, also known as disseminate and recurrent infundibulofolliculitis, presents as a follicular, often pruritic, papular eruption with a predilection for the trunk and proximal parts of the extremities of young adult males.⁶⁴⁻⁶⁷ It occurs almost exclusively in black patients. Although the lesions resemble those seen in some cases of atopic dermatitis, the individuals studied so far have not been atopic.⁶⁸

Figure 5.9 Follicular spongiosis. The patient had follicular lesions on the trunk as a manifestation of atopic dermatitis. (H&E)

Histopathology^{64,66,68}

There is spongiosis of the follicular infundibulum with exocytosis of lymphocytes (Fig. 5.10). A few neutrophils are sometimes present. There is widening of the follicular ostium and focal parakeratosis of the adjacent epidermis. Occasional follicles contain a keratin plug.⁶⁸ The follicular infundibulum is often hyperplastic. There is usually a slight infiltrate of lymphocytes around the follicles and around the blood vessels in the superficial part of the dermis. Mast cells may be increased.

ATOPIC DERMATITIS (FOLLICULAR LESIONS)

Some patients with atopic dermatitis develop small follicular papules, often on the trunk.

Histopathology

There is spongiosis of the follicular infundibulum with exocytosis into this region of the epidermis. Usually, no neutrophils are present. The adjacent epidermis may show mild acanthosis and sometimes

Figure 5.10 Infundibulofolliculitis. There is follicular spongiosis, focal parakeratosis, and a mild inflammatory cell infiltrate in the dermis. (H&E)

focal parakeratosis. The histopathology resembles that seen in infundibulofolliculitis.

APOCRINE MILIARIA

Apocrine miliaria (Fox–Fordyce disease) presents as a chronic papular eruption, usually limited to the axilla (see p. 503). It results from rupture of the intra-infundibular portion of the apocrine duct.

Histopathology

Serial sections may be required to demonstrate the spongiosis of the follicular infundibulum adjacent to the point of entry of the apocrine duct. There may be a few neutrophils in the associated inflammatory response. Periductal foam (xanthoma) cells are often present.

EOSINOPHILIC FOLLICULITIS

Eosinophilic folliculitis (Ofuji's disease) is characterized by eosinophilic spongiosis centered on the follicular infundibulum. It is discussed in detail on page 463.

PITYRIASIFORM SPONGIOSIS

Pityriasiform spongiosis is characterized by the presence of microvesicles within areas of spongiosis that contain lymphocytes, histiocytes, and Langerhans cells. It is a distinctive pattern when well developed. It is seen in the following conditions:

- Pityriasis rosea
- Pityriasiform drug reaction
- Erythema annulare centrifugum
- Nummular dermatitis (some cases)
- Lichen striatus (uncommon).

The spongiosis in miliaria may mimic pityriasiform spongiosis but the vesicles are often larger, and they are always related to an acrosyringium. The 'inverted flask'-like lesions sometimes seen in allergic contact dermatitis are better defined microvesicles, with a different shape to pityriasiform lesions. They also contain a predominance of Langerhans cells.

The various diseases are discussed in order, but nummular dermatitis (see p. 120) and lichen striatus (see p. 50) are considered in more detail elsewhere.

PITYRIASIS ROSEA

Pityriasis rosea is a common, acute, self-limited dermatosis in which oval, salmon-pink, papulosquamous lesions develop on the trunk, neck, and proximal extremities.⁶⁹ Lesions often follow the lines of skin cleavage, giving a 'Christmas tree' pattern.⁷⁰ A scaly plaque 2–10 cm in diameter, the 'herald patch', may develop on the trunk 1 or 2 weeks before the other lesions. Pityriasis rosea has been reported at all ages,⁷¹ but the majority of patients are between 10 and 35 years old.⁷² Clinical variants include those with acral⁷³ or facial involvement,⁷¹ oral lesions,⁷⁴ a unilateral or local distribution,^{75,76} or the presence of pustular, purpuric, or vesicular lesions.^{69,77–80} Follicular pityriasis rosea is a rarely reported form of the disease.⁸¹ Pityriasis rosea developing in the first 15 weeks of pregnancy is associated with premature delivery and miscarriages.⁸²

Because atypical cases of pityriasis rosea are fairly common,^{83,84} Chuh has drawn up a list of diagnostic criteria for pityriasis rosea.^{85,86} *Essential* features for the diagnosis include (1) discrete circular or oval lesions, (2) scaling on most lesions,⁸⁷ and (3) peripheral collarette scaling with central clearance of at least two lesions. *Optional* clinical features, of which one must also be present, include (1) truncal and proximal limb distribution, with less than 10% of lesions distal to the mid-upper arm and mid thigh; (2) distribution of most lesions along the ribs; and (3) a herald patch appearing at least 2 days before the generalized eruption.⁸⁵ Interestingly, histopathological features were not added to the criteria "because they are nonspecific in PR."⁸⁵ Pityriasis rosea must be distinguished from secondary syphilis.^{85,88} Ackerman proposed that pityriasis rosea and erythema annulare centrifugum are clinical variations of a single pathological process, and that pityriasis rosea gigantea is pityriasis rosea concurrent with erythema annulare centrifugum.⁸⁹

The etiology is unknown, but an infectious etiology, particularly a virus, has long been suspected. This is supported by a history of a preceding upper respiratory tract infection in some patients;⁹⁰ occasional involvement of close-contact pairs;⁷² case clustering;^{91,92} modification of the disease by the use of convalescent serum or erythromycin;^{79,93} and the development of a pityriasis rosea-like eruption in some cases of infection by ECHO 6 virus, enterovirus, or *Mycoplasma*.^{69,94} There has been recent interest in the role of human herpesvirus-6 (HHV-6) and HHV-7 in the etiology of pityriasis rosea. Although HHV-6 and HHV-7 may play a role in some patients,^{95–99} the low detection rate of HHV-7 DNA sequences argues against a causative role for this virus.^{100–104} In the case of HHV-6, reactivation of the virus during the early stages of the disease might explain its detection in some cases.¹⁰⁵ Herpesvirus-like particles were detected in lesional skin in 71% of patients with pityriasis rosea in one study.¹⁰⁶ Pityriasis rosea is not associated with HHV-8 infection¹⁰⁷ or with HSV-1 or HSV-2 infection.¹⁰⁸ Particles resembling togavirus or arenavirus have been found on electron microscopy of a herald patch,¹⁰⁹ suggesting that this might be the inoculation site. An association with influenza A (H1N1) infection has also been reported.^{110,111} No virus has ever been cultured.¹¹² Immunological reactions,¹¹³ particularly cell-mediated, have also been regarded as important.^{114,115} Certain HLA subtypes may confer a susceptibility to the disease in certain races.¹¹⁶

A pityriasis rosea-like eruption has also been recorded as a complication of graft-versus-host reaction, following bone marrow transplantation,¹¹⁷ and in patients with acute myeloid leukemia¹¹⁸ or Hodgkin's disease.⁸⁴ A long-lasting pityriasis rosea-like eruption has been described in association with AIDS.⁸⁸ The occurrence of a pityriasis rosea-like

Figure 5.11. Pityriasis rosea. An example of a parakeratotic mound is shown. (H&E)

eruption in a patient with indeterminate cell histiocytosis may have resulted from an isotopic response in healed lesions of pityriasis rosea.⁷⁰

It is debatable whether active intervention is warranted to modify the disease course.¹¹⁹ Spontaneous resolution often occurs within 4–8 weeks.⁸⁸ Benefit has been reported from erythromycin⁹⁴ and high-dose¹²⁰ or low-dose¹²¹ acyclovir (aciclovir). Evidence does not clearly support the use of UV phototherapy⁸⁸ or corticosteroids.⁸⁸ Also, just as in infectious mononucleosis, ampicillin may exacerbate the disease, producing more lesions, an abnormal distribution of lesions, and a prolonged clinical course.¹²²

Histopathology^{114,123,124}

Although the lesions are clinically papulosquamous, microscopy shows a spongiotic tissue reaction. The histopathological features are not pathognomonic, although in most cases they are sufficiently characteristic to allow the diagnosis to be made, even without a clinical history. The epidermis often has a vaguely undulating appearance. There is usually focal parakeratosis, sometimes with the formation of parakeratotic mounds (Fig. 5.11). Sometimes these mounds partly lift from the epidermis, giving a tilted appearance to the mound.¹²⁵ There is a diminution of the granular layer and focal spongiosis of pityriasiform type with lymphocyte exocytosis (Fig. 5.12). Small spongiotic vesicles, sometimes simulating Pautrier microabscesses because of the aggregation of lymphocytes within them, are a characteristic feature; they are present in most cases if several levels are examined. Dyskeratotic cells may be seen at all levels of the epidermis; they are more common in the herald patch. Apoptotic keratinocytes are present in the lower epidermis in lesions undergoing involution. Multinucleate epidermal cells are uncommon. Focal acantholytic dyskeratosis has been reported once.¹²⁶

The papillary dermis shows some edema and sometimes homogenization of collagen. There may be some melanin incontinence. Red cell extravasation is common in the upper dermis and may extend into the lower layers of the epidermis (Fig. 5.12D). There is a mild to moderate lymphohistiocytic infiltrate in the upper dermis, with some eosinophils in the infiltrate in older lesions. The rare follicular variant shows follicular spongiosis, sometimes follicular plugging, and papillary dermal erythrocyte extravasation.⁸¹

Dermoscopic features helpful in the diagnosis of pityriasis rosea include a yellowish background, dotted vessels, and peripheral scales.¹²⁷

Electron microscopy

Ultrastructural examination has confirmed the presence of dyskeratotic cells in some patients.¹²⁸ These cells show aggregation of tonofilaments, some cytoplasmic vacuoles, and intracytoplasmic desmosomes.¹²⁹ Cytolytic degeneration of keratinocytes adjacent to Langerhans cells has been reported in a herald patch.¹³⁰ Virus-like particles have been seen in several studies.^{107,128}

PITYRIASIFORM DRUG REACTION

Pityriasiform (pityriasis rosea-like) drug reaction presents as an eruption that resembles to varying degrees pityriasis rosea, usually within weeks of commencing one of the drugs listed in Table 5.2. There are usually fewer lesions in drug-related cases than in pityriasis rosea. They are often larger than in pityriasis rosea, with scaling involving the entire lesion.⁶⁹ Drug-related cases usually lack a herald patch.¹³¹ Furthermore, oral lesions are more common, as is the development of postinflammatory hyperpigmentation.⁸⁸

Many drugs have been implicated in the etiology of these eruptions,⁶⁹ including gold, bismuth, arsenicals, ketotifen, clonidine, barbiturates, omeprazole,¹³¹ tiopronin, terbinafine, benfluorex,¹³² pyribenzamine, penicillamine, isotretinoin, metronidazole,¹³³ captopril,¹³⁴ lisinopril,¹³⁵ imatinib mesylate,^{136,137} and adalimumab.¹³⁸ The latter case cleared 2 weeks after cessation of the drug, making this diagnosis more likely than pityriasis rosea associated with lowered immunity from the drug.¹³⁸ Other agents include nortriptyline¹³⁹ and rituximab.¹⁴⁰

Cases have also been associated with bacillus Calmette–Guérin (BCG),^{88,141} pneumococcal,¹⁴² and influenza (H1N1) vaccinations.¹⁴³

Histopathology

There is pityriasiform spongiosis with variable resemblance to pityriasis rosea. Eosinophils are invariably present, but they may also be found in later lesions of pityriasis rosea. Apoptotic keratinocytes are features in both conditions, but only in later lesions of pityriasis rosea. Subepidermal edema may also be present in drug-related cases.

ERYTHEMA ANNULARE CENTRIFUGUM

Erythema annulare centrifugum is a pityriasiform dermatosis that in some stages of its evolution is indistinguishable from pityriasis rosea. There are one or more annular, erythematous lesions that may spread outward or remain stationary. A fine scale is sometimes present inside the advancing edge, giving a so-called ‘trailing scale’ (see p. 259). The annular erythema of Sjögren’s syndrome is sometimes spongiotic.¹⁴⁴

Until recently, erythema annulare was included with other erythemas in the lymphocytic vasculitides, although this was always regarded as unsatisfactory. The detailed studies of Weyers and colleagues delineated the histological appearances of this entity.¹⁴⁵ For various reasons, the main discussion of this entity is in Chapter 8.

Histopathology

A biopsy through the advancing edge will show focal spongiosis and parakeratosis with an underlying superficial perivascular infiltrate of lymphocytes, often with a ‘coat-sleeve’ appearance. There are some similarities to pityriasis rosea, although a biopsy taken at right angles to the edge of erythema annulare centrifugum will show a much more localized process. A ‘variant’ without spongiosis and with a deep as well as superficial inflammatory infiltrate also occurs. This is probably a different entity.¹⁴⁵

Figure 5.12 Pityriasis rosea. (A) A typical case with pityriasiform spongiosis. (B) A more 'florid' case with several foci of pityriasiform spongiosis and subepidermal edema. (C) In this case, the dermal inflammation is quite mild. (H&E) (D) Erythrocytes can be identified in dermal papillae. This image also shows 'tilting' of a parakeratotic mound. (H&E)

Table 5.2 Drug and vaccine causes of a pityriasis rosea-like eruption	
Adalimumab	Ketotifen
Arsenicals	Lisinopril
Barbiturates	Metronidazole
BCG vaccination	Nortriptyline
Benfluorex	Omeprazole
Bismuth	Penicillamine
Captopril	Pneumococcal vaccination
Clonidine	Pyribenzamine
Gold	Rituximab
Imatinib mesylate	Smallpox vaccination
Influenza (H1N1) vaccination	Terbinafine
Isotretinoin	Tiopronin

Note: Ampicillin may exacerbate pityriasis rosea.

OTHER SPONGIOTIC DISORDERS

Most of the other diseases in which the spongiotic reaction pattern occurs show spongiosis distributed randomly through the epidermis with no specific localization to the acrosyringium or follicular infundibulum, which indeed are often spared.

It is sometimes quite difficult to make a specific histopathological diagnosis of some of the diseases in this category. Often, a diagnosis of 'spongiotic dermatitis consistent with ...' is as specific as one can be.

Miscellaneous diseases that may sometimes show epidermal spongiosis include Still's disease,¹⁴⁶ prurigo pigmentosa (it is often neutrophilic in type; see p. 339), and dermal hypersensitivity reaction (see p. 1134). The spongiosis is rarely of eosinophilic type in adult-onset Still's disease.²³

IRRITANT CONTACT DERMATITIS

Irritant contact dermatitis is an inflammatory condition of the skin produced in response to the direct toxic effect of an irritant

substance.¹⁴⁷ It accounts for approximately 80% of occupational skin diseases.¹⁴⁸ The most commonly encountered of these irritants include detergents, solvents, acids, and alkalis.^{147,149,150} Other agents include wool fibers,¹⁵¹ fiberglass,^{151–153} air bags,¹⁵⁴ topical anesthetic agents,¹⁵⁵ sunscreen preparations,¹⁵⁶ propylene glycol,¹⁵⁷ and plants,¹⁵⁸ particularly the milky sap of members of the family Euphorbiaceae.^{159,160} Garlic applied to the skin may produce a severe irritant dermatitis resembling a chemical burn.¹⁶¹ Even airborne substances in droplet, particulate, or volatile form can cause this type of dermatitis.¹⁶² Chemically induced irritant contact dermatitis is a leading cause of occupational disease with important economic consequences;¹⁶³ accordingly, protective creams are being developed and evaluated to assist in the control of this important problem.^{164,165} Protective gloves can also be used, but selection of gloves made of appropriate material is necessary to avoid exacerbation of the original process.¹⁶⁶

Our knowledge of irritant contact dermatitis is limited despite the fact that it is more common than allergic contact dermatitis (although this has been challenged recently), from which it may be difficult to distinguish.^{167,168} Irritant reactions vary from simple erythema to purpura, eczematous reactions, vesiculobullous lesions, and even epidermal necrosis with ulceration. Lesions are often more glazed than allergic reactions and subject to cracking, fissuring, and frictional changes.¹⁴⁹ Irritant reactions occur at the site of contact with the irritant; in the case of airborne spread, the eyelids are a common site of involvement.^{162,169} Pustular reactions have been reported with heavy metals, halogens, and other substances.^{170,171} These responses are assumed to be irritant in type. Acute ulceration is a severe reaction that may follow contact with alkalis, including cement.^{172,173} Ten clinical subtypes of irritant contact dermatitis were listed in the review of this topic by Rosemary Nixon and colleagues in 2008.¹⁶⁸ They are listed in **Table 5.3**.

Irritant contact dermatitis appears to have a predilection for the vulva.¹⁷⁴ Irritating substances include antiseptics, douches, lubricants, contraceptives, and sanitary pads.¹⁷⁴ Friction and overheating also play a role in exacerbating any inflammatory process. The histological appearance often mimics that of allergic contact dermatitis.¹⁷⁴

A special variant of irritant contact dermatitis is seen in association with urostomies. Encopresis is another cause of this disorder.¹⁷⁵ Eventually, pseudoverrucous papules and nodules may develop in the

perianal region.¹⁷⁶ Other stomas may also be associated with irritant reactions.¹⁷⁷ Granuloma gluteale infantum (a misnomer because there are no granulomas) is a diaper-related irritant dermatitis in which *Candida albicans* may also play a role (see p. 693).¹⁷⁸ It is now thought that granuloma gluteale, pseudoverrucous papules, and Jacquet's erosive diaper dermatitis are parts of a disease spectrum that may be multifactorial in origin but with a primary irritant etiology.¹⁷⁹ A similar erosive papulonodular dermatosis has resulted from the topical use of benzocaine.¹⁷⁹

Susceptibility to irritant dermatitis is variable, although approximately 15% of the population have heightened sensitivity of their skin that appears to result from a thin, permeable stratum corneum.¹⁶⁷ There are differences in skin sensitivity in different regions of the body.^{180,181} Atopic individuals are more susceptible,¹⁸² and both irritants and an atopic diathesis have been incriminated in the etiology of occupational dermatitis of the hands.^{167,183–185} Loss-of-function polymorphisms in the filaggrin gene (*FLG*) are associated with an increased susceptibility to chronic irritant contact dermatitis.¹⁸⁶ African American skin appears to have superior barrier function to irritants compared to white skin.¹⁴⁸ Cumulative irritancy, in which multiple subthreshold damage to the skin occurs, may also be seen with agents in cosmetics, for example.^{149,163,187} Delayed irritancy is another variant of irritant contact dermatitis in which the clinical changes are not manifest until 8–24 hours after the exposure.¹⁸⁸ Susceptibility to irritants is also more common in the winter months, apparently as a result of changes in the barrier functions of the stratum corneum.¹⁸⁹ Low humidity due to air-conditioning can result in an irritant contact dermatitis of the face and neck in office workers due to drying out of the skin.¹⁹⁰ Physical friction is also an important contributor to contact dermatitis, particularly the irritant type.¹⁹¹ Minor frictional trauma may cause enhanced penetration of allergens.¹⁹¹

Irritants may act in several different ways. They may remove surface lipids and water-holding substances (as with surfactants contained in household cleaning products),^{192,193} damage cell membranes, or denature epidermal keratins.¹⁹⁴ They may have a direct cytotoxic effect. Some irritants are also chemotactic for neutrophils *in vitro*, whereas others may lead to the liberation of cytokines and other inflammatory mediators; tumor necrosis factor has been implicated as an important cytokine in irritant reactions.¹⁸⁷ The pathogenesis of irritant contact dermatitis continues to be poorly understood, although evidence is emerging that a very complex reaction pattern occurs, involving immunoregulatory processes.^{167,195,196} Irritancy may also lead to allergic contact dermatitis.¹⁹⁷

Cytokine expression in allergic and irritant contact reactions differs surprisingly little.¹⁹⁸ They are similar at 72 hours after the application of the respective experimental contactant, although at 6 hours, the irritant reaction expresses higher levels.¹⁹⁹ Cytokines that are increased include interleukin (IL)-1 α , IL-1 β , IL-2, IL-6, interferon- γ (IFN- γ), and tumor necrosis factor- α (TNF- α).^{198,199} The chemokine CCL21, produced by dermal lymphatic endothelial cells, is upregulated in irritant contact dermatitis.¹⁶⁸ It facilitates the migration of naive T lymphocytes, resulting in a skin inflammatory response. Apoptosis of epidermal Langerhans cells is produced by some irritants but not others.²⁰⁰ Recent work has emphasized the importance of certain gene polymorphisms in irritant contact dermatitis. In particular, individuals with TNF- α polymorphism 308 appear to be more prone, and those with TNF- α polymorphism 238 less prone, to irritant contact dermatitis;^{201,202} IL-1 α polymorphism 889 may actually offer a protective effect against irritant dermatitis.²⁰³ Strongly irritant substances have been shown to induce intracellular calcium in normal human keratinocytes; this is measurable by spectrofluorimetry, which may be a convenient method of determining potential reactions to certain irritating compounds.²⁰⁴

Avoiding exposure to irritants, the use of protective equipment, and the use of moisturizing creams are the bases of treatment.¹⁶⁸ A

Table 5.3 Clinical subtypes of irritant contact dermatitis (ICD)	
Types	Features
Acute ICD	Caused by potent irritant
Delayed acute ICD	Reaction 8–24 hours after exposure
Irritant reaction	Seen with wet work
Sensorial irritation	Sensory discomfort, no clinical lesion; lactic acid, propylene glycol are causes
Non-erythematous irritation	Clinically normal, histologically apparent; consumer products with high content of surfactants are causes
Cumulative ICD	Most prevalent; multiple subthreshold insults from weak irritants
Traumatic ICD	Follows acute skin trauma, such as acute dermatitis or a burn
Pustular and acneiform ICD	Metals, tars, oils, chlorinated agents, cosmetics
Asteatotic ICD	In elderly patients; dry skin
Frictional ICD	Confined to locations of frictional trauma; often appears psoriasiform

systematic review of the treatment and prevention of irritant contact dermatitis found that barrier creams containing dimethicone or perfluoropolyethers, cotton liners, and softened fabrics prevent irritant contact dermatitis. Lipid-rich moisturizers both prevent and treat this condition.²⁰⁵ Topical corticosteroids and macrolide immunomodulators have also been used. Recent work suggests that topical corticosteroids may compromise barrier function.¹⁶⁸ Cumulative irritant contact dermatitis has been treated by phototherapy.¹⁶⁸

Chronic hand eczema

This condition is included in the discussion of irritant contact dermatitis because of the significant role of various irritants in most cases, despite the fact that there are actually several different subtypes of hand eczema. Based on her extensive experience, Storrs recognizes six categories: (1) allergic, (2) irritant, (3) nummular, (4) dyshidrotic, (5) chronic vesicular,^{206,207} and (6) hyperkeratotic.²⁰⁸ Hybrid forms with overlapping features of different types are common. A scoring system for the severity of hand eczema has been proposed.²⁰⁹ Patch testing is vital in the diagnostic workup of patients with hand dermatitis.^{209,210} The most common allergens involved in one series of patients with allergic contact dermatitis of the hands were preservatives, metals, fragrances, topical antibiotics, and rubber additives.²¹⁰ Wet work and genetic factors also play a role.²¹¹ Fungal infection (tinea manuum) should also be excluded. The role of an atopic diathesis in the etiology of irritant hand dermatitis is mentioned later.

Management of chronic hand eczema includes identification and elimination of possible contact allergens, topical steroid ointments and tars,²⁰⁸ additions of zinc sulfate cream²¹² or salicylic acid (5%), short courses of systemic steroids for pompholyx and the chronic vesicular form of the disease,²⁰⁸ restoration of the natural lipid barrier of the epidermis with topical ceramides (which rarely may be a cause of contact dermatitis),²⁰⁸ and management of refractory cases with oral alitretinoin (9-*cis* retinoic acid).²¹³

Histopathology

The changes observed in irritant contact dermatitis vary with the nature of the irritant, including its mode of action and its concentration.^{194,214} A knowledge of these factors helps to explain the conflicting descriptions in the literature.²¹⁵ Furthermore, many of the histopathological studies have been performed on animals, which are particularly liable to develop epidermal necrosis and dermoepidermal separation with neutrophil infiltration when exposed to high concentrations of irritants.^{214,216} In humans, high concentrations of an irritant will produce marked ballooning of keratinocytes in the upper epidermis with variable necrosis ranging from a few cells to confluent areas of the epidermis.^{217–219} Neutrophils are found in the areas of ballooning and necrosis, and mild spongiosis is also present in the adjacent epidermis (Fig. 5.13).²¹⁹

If low and medium concentrations of an irritant are applied, the histopathological spectrum of the reactions produced often mimics that seen in allergic contact dermatitis, with epidermal spongiosis, mild superficial dermal edema, and a superficial, predominantly perivascular infiltrate of lymphocytes (Fig. 5.14).^{214,215,220} The lymphocytes are of helper/inducer type.¹⁴⁷ Langerhans cells are found diffusely through the upper dermis from day 1 to day 4 following contact with the irritant; this is in contrast to allergic contact dermatitis, in which these cells are more perivascular in location and persist in the dermis for a longer period.¹⁴⁷ Occasional apoptotic keratinocytes may be seen in the epidermis in irritant reactions.^{221,222} In the recovery phase of irritant dermatitis, mild epidermal hyperplasia is often present. Psoriasiform hyperplasia may develop in chronic irritant reactions.

Pustular reactions show subcorneal vesicles with neutrophils, cellular debris, and a fibrinous exudate. There are also some neutrophils in the upper dermal infiltrate.

Figure 5.13 Irritant contact dermatitis (A) with superficial epidermal necrosis, edema, and some neutrophils. **(B)** There is focal ballooning and necrosis of keratinocytes in the upper epidermis together with spongiosis and a mild infiltrate of neutrophils. **(C)** There is full-thickness epidermal necrosis with subepidermal clefting. (H&E)

Figure 5.14 Mixed irritant and allergic contact dermatitis. (H&E)

A detailed study using various irritants and human volunteers confirmed the marked variability in histopathological responses, depending on the chemical used.¹⁹⁴ For example, propylene glycol produced hydration of corneal cells and a prominent basket-weave pattern.¹⁹⁴ Non-anoic acid resulted in tongues of eosinophilic keratinocytes with shrunken nuclei in the upper epidermis; croton oil caused a spongiotic tissue reaction resembling allergic contact dermatitis.¹⁹⁴ Sodium lauryl sulfate produced a thick zone of parakeratosis; dithranol caused some basal spongiosis and pallor of superficial keratinocytes; and benzalkonium resulted in mild spongiosis, sometimes accompanied by foci of necrosis in the upper spinous layers.¹⁹⁴ The ultrastructural changes also varied widely with the different irritants.¹⁹⁴ It is obvious that further studies using other potential human irritants are needed to increase our understanding of the diversity of irritant reactions.

ALLERGIC CONTACT DERMATITIS

Allergic contact dermatitis is an important dermatological disease with considerable morbidity and economic impact.²²³ It is an inflammatory disorder that is initiated by contact with an allergen to which the person has previously been sensitized.^{147,188} The prevalence of contact dermatitis (both irritant and allergic) in the general population in the United States has been variably estimated to be between 1.5% and 5.4%.¹⁶⁷ It is uncommon in children.^{224,225} Allergic contact dermatitis has always been thought to be less frequent than irritant dermatitis, but recent studies show the reverse to be the case.²²⁶ Both are a significant occupational problem.^{227,228} Hairdressers are one of the largest groups affected by occupational contact dermatitis.²²⁹ This risk is heightened if underlying atopy is present.²³⁰ The use of hair dyes is an important contributor to this problem.²³¹ Veterinarians are prone to develop contact dermatitis on the hands and forearms.²³² Athletes are another group of individuals who confront a range of irritants and allergens. This subject was reviewed in 2007.²³³ Pool toes, a sports-related dermatosis of swimmers, is an allergic contact dermatitis to cement.²³⁴ Jogger's nipples, an eczematous disease of the nipples occurring in joggers, has a multifactorial etiology, including underlying atopy.²³⁵

Clinically, there may be erythematous papules, small vesicles, or weeping plaques, which are usually pruritic. The lesions develop 12–48 hours after exposure to the allergen. In the case of cosmetic reactions, the face, eyelids, and neck are commonly involved, but the lesions may extend beyond the zone of contact, in contrast to irritant reactions.^{236,237} Eyelid dermatitis is a multifaceted clinical problem, but allergic contact dermatitis is a common cause, even among those with atopic

eczema.²³⁸ Eye drops containing phenylephrine hydrochloride have also resulted in a contact reaction of the eyelids.²³⁹ Cheilitis is another regional dermatitis that may be due to constituents of mouthwash²⁴⁰ and lipstick.²⁴¹ Anogenital dermatitis is another localized form of contact dermatitis.^{242,243} With occupational exposures, the hands are frequently involved.^{207,244,245} An uncommon cause of hand dermatitis is contact with the nargile (Turkish water pipe).²⁴⁶ Stasis dermatitis of the lower parts of the legs is particularly susceptible to allergic contact reactions.²⁴⁷ Contact sensitivity is also increased in patients with past or present leg ulcers.²⁴⁸ Rarely reported allergic reactions include follicular or pustular lesions,^{249,250} systemic contact reactions; and urticarial,²⁵¹ granulomatous,²⁵² leukodermic,²⁵³ or erythema multiforme-like lesions.^{254–256} Pustular contact dermatitis has developed on the scalp following the use of topical minoxidil.²⁵⁰ Purpuric lesions, which may go on to resemble pigmented purpuric dermatosis, are a rare manifestation of contact allergy. They usually result from contact with resins or textile dyes, particularly Disperse Blue.^{257–259} Resolution of allergic contact dermatitis usually occurs 2 or 3 weeks after the withdrawal of the relevant allergen or cross-sensitizing agent.

Two patients have been reported with long-standing pustular psoriasis who developed coexistent allergic contact dermatitis.²⁶⁰

Etiology of allergic contact dermatitis

Numerous agents, including more than 3000 chemicals,²⁶¹ have been incriminated in the etiology of allergic contact dermatitis.²⁶² They include cosmetics,²⁶³ foodstuffs, plants,^{264,265} topical medicaments, and industrial chemicals.²⁶⁶ Reactions to cosmetics may result from the fragrances,²⁶⁷ preservatives,^{268–271} or lanolin base.^{236,272–284} An expired moisturizer (sorbolene cream) has also been incriminated, probably due to the development of degradation products in the cream.²⁸⁵ Cinnamic aldehyde in deodorants is an important cause of axillary dermatitis.²⁸⁶ A substantial number of reactions occur to the four fragrance chemicals cinnamal/cinnamic alcohol and isoeugenol/eugenol.^{287–289} Kumkum, a colored cosmetic used by Hindu women, is an important cause of a contact dermatitis.^{230,290} Another constituent of fragrances, oxidized citrus oil (R-limonene), is a frequent skin sensitizer in Europe.²⁹¹ Foodstuffs that have been implicated include flavorings, spices,²⁹² animal and fish proteins, olive oil,²⁹³ flour additives,²⁹⁴ citrus fruits,²⁹⁵ shiitake mushrooms,^{296,297} macadamia nuts,²⁹⁸ mangos,^{299,300} cinnamon,³⁰¹ onions, spinach,³⁰² broccoli,³⁰³ asparagus,³⁰⁴ garlic, and chives.^{305–308} Preservatives used in animal feed and in other industries may produce an occupational dermatitis.^{309,310} The plants include poison ivy,^{311–317} other species of *Rhus*,³¹⁸ various members of the Compositae family,^{311,319–323} melaleuca (tea tree) oil,^{324–326} the latex of mangrove trees,³²⁷ *Agave americana*,³²⁸ tulips,³²⁹ hydrangea,³³⁰ sunflower,³³¹ and *Alstroemeria* (Peruvian lily).^{332,333} Botanical ingredients, such as lichens, used in personal care products such as deodorants, are an under-reported cause of allergic contact dermatitis.³³⁴ Plant particles and some chemicals may give rise to contact reactions by airborne spread.^{169,335–337} In the past, topical medicaments such as penicillin, sulfonamides, mercurials, and antihistamines were the most common sensitizers.³³⁸ Currently, neomycin and other topical antibiotics,³³⁹ benzocaine, ethylenediamine (a stabilizer), parabens preservatives, and propylene glycol are common causes of such reactions.^{157,338,340,341} Other sensitizers, mostly industrial based, include potassium dichromate, gold,^{342–344} mercury,³⁴⁵ nickel salts (discussed later), cobalt,^{346,347} chromate,^{347,348} formaldehyde,³⁴⁹ formaldehyde-releasing preservatives,³⁵⁰ phenol-formaldehyde resin,³⁵¹ chemicals in rubber,^{352–357} natural rubber latex,^{229,358,359} color film developers,³⁶⁰ acrylic and epoxy resins,^{361–366} acrylates in artificial nails,^{367,368} cyanoacrylate in topical skin adhesives,³⁶⁹ immersion oil,^{335,370} coloring agents, henna,^{371,372} 'paint-on' tattoos,^{373–378} textile dyes,^{379–385} disposable gloves,^{386–388} sanitary pads,³⁸⁹ baby wipes,³⁹⁰ cinnamic aldehyde,²⁸⁶ compound tincture of benzoin,³⁹⁰ quaternium-15,³⁹¹ and phenylenediamine.^{392,393} Less common causes

include doxepin cream,^{394,395} ciclopirox olamine (topical antifungal),³⁹⁶ topical calcipotriol,³⁹⁷ vitamin E preparations,³⁹⁸ lanolin,³⁹⁸ topical corticosteroids,^{399–417} nonsteroidal anti-inflammatory drugs (NSAIDs),^{418,419} tacrolimus ointment,⁴²⁰ pimecrolimus,⁴²¹ infliximab,⁴²² bacitracin,⁴²³ mupirocin,⁴²⁴ topical minoxidil,²⁵⁰ enoxolone,⁴²⁵ lanconazole,⁴²⁶ miconazole,⁴²⁷ propacetamol,⁴²⁸ surgical adhesive materials,^{369,429,430} thiourea in a neoprene knee brace,⁴³¹ topical amide anesthetics,^{432–436} idoxuridine,⁴³⁷ tefillin (phylacteries),⁴³⁸ Unna boots,⁴³⁹ other footwear,^{440–442} laundry detergents,⁴⁴³ benzalkonium chloride,⁴⁴⁴ pentyleneglycol,⁴⁴⁵ plastic banknotes,⁴⁴⁶ air bags,¹⁵⁴ cellular phones,⁴⁴⁷ oils used in aromatherapy,^{448–450} antiseptic bath oils,^{451–453} anethole in spearmint-flavored toothpaste,⁴⁵⁴ tear gas (2-chloroacetophenone),^{455,456} fluorouracil,⁴⁵⁷ 5-aminolevulinic acid methylester used in photodynamic therapy,⁴⁵⁸ and psoralens.⁴⁵⁹ Xylitol, a sweetener in chewing gum, can cause an oral erosive 'eczema'.⁴⁶⁰ Allergic contact dermatitis can be provoked or intensified by chemically related substances. These cross-sensitization reactions are an important clinical problem.³³⁸ Inhalation of corticosteroids in the treatment of asthma may reactivate allergic contact dermatitis in individuals with prior skin reactions to topical corticosteroids.⁴⁶¹ Information on contact dermatitis and the Contact Allergen Replacement Database can be obtained from the American Contact Dermatitis Society website at <http://www.contactderm.org>.²⁶¹ The European Surveillance System of Contact Allergies (ESCA) collects data and monitors the situation in Europe.⁴⁶²

Nickel allergy is an important cause of morbidity, especially from hand dermatitis.^{463–471} Loss-of-function mutations in the filaggrin (*FLG*) gene, which are also seen in atopic dermatitis, may represent a risk factor for contact sensitization to various allergens, including nickel.⁴⁷² The prevalence of nickel allergy is much lower in men; there is evidence that ear piercing followed by the use of nickel-containing earrings accounts for this difference.^{464,473,474} Nickel allergy is important in children. Belt buckles may produce an umbilical dermatitis, sometimes associated with a papular id reaction.^{475–477} Nickel-containing coins have also been incriminated as a risk factor for allergic contact dermatitis of the hands.^{478–480} Avoidance of skin contact with and dietary intake of nickel is difficult to achieve.⁴⁶⁷ A European Union directive to reduce nickel release in consumer products has had a beneficial effect. Nickel exposure from inexpensive earrings in the United States, where no such directive exists, is an important source of nickel exposure.⁴⁸¹ Cosensitizations to copper,⁴⁸² cobalt, and chromate are sometimes present.⁴⁸³ Chromium-related dermatitis has an onset in later working life and often affects those in the building trades.³⁴⁷ In contrast, cobalt-related dermatitis has an earlier onset and may affect a wide range of employments.³⁴⁷ Allergy to metal implants is an increasing clinical problem. It is discussed with systemic contact reactions (see p. 129).

The specific allergen responsible for allergic contact dermatitis can be identified using a patch test.^{484–489} However, these reactions are not always reproducible at sequential or concomitant testing. In the United States, the commonly used patch test procedure is the TRUE (thin-layer rapid-use epicutaneous) test.²²³ Analysis of results produced by these tests has shown that nickel (14.7% of tested patients), thimerosal (5.0%), cobalt (4.8%), fragrance mix (3.4%), and balsam of Peru (3.0%) are the most prevalent allergens.²²³ In contrast, the North American Contact Dermatitis Data Group (NACDGD) data show that the most prevalent allergens are nickel (14.3%), fragrance mix (14%), neomycin (11.6%), balsam of Peru (10.4%), and thimerosal (10.4%).²²³ The prevalence of allergy to cobalt in this database is 9.2%.²²³ Reactions to fragrances, rubber accelerators, pesticides, and formaldehyde may be missed with the TRUE test.⁴⁹⁰ There is evidence that constituents of the patch test panel may sometimes produce active sensitization.⁴⁹¹ Confocal reflectance microscopy has been used to study allergic and irritant contact dermatitis.^{492,493} Initial studies are promising, but it is an adjunctive tool rather than a substitute for clinical evaluation.⁴⁹⁴

Pathogenesis of allergic contact dermatitis

Allergic contact dermatitis is a special type of delayed hypersensitivity reaction.^{495,496} In cases produced by chemicals, an associated irritant reaction is often present.⁴⁹⁷ Furthermore, an irritant contact dermatitis facilitates allergic contact sensitization.⁴⁹⁸ The compound responsible for the allergic reaction is usually of low molecular weight (a hapten) and lipid soluble.⁴⁹⁹ After penetrating the skin, the hapten becomes bound to a structural or cell surface protein, usually by a covalent bond, thus forming a complete antigen.^{167,500,501} This antigen is processed by Langerhans cells, other dendritic cells,⁵⁰² and possibly macrophages,⁵⁰³ and then it is presented to T lymphocytes.^{504,505} The actual way in which the Langerhans cells interact with the antigen and lymphocytes is not known, although the dendritic nature of Langerhans cells obviously assists in their antigen-presenting role.^{167,506,507} Various regulatory proteins also influence the function of these dendritic cells.⁵⁰⁸ Keratinocyte-derived cytokines influence this initial phase of the response.⁵⁰⁹ Keratinocytes can mature functionally and become potent antigen-presenting cells in the same way that Langerhans cells do.⁵¹⁰ This induction phase is followed by migration of T lymphocytes to the regional lymph nodes where there is clonal expansion of specifically sensitized lymphocytes.⁴⁶³ On second and subsequent exposures to the allergen, the elicitant response occurs with proliferation of T lymphocytes in both the skin and the regional lymph nodes.^{423,499,511} There is activation of T cells of both CD4⁺ Th1 and CD8⁺ Tc1 types.⁵¹² The homing of lymphocytes to the antigen-exposed skin involves various cell adhesion molecules, such as lymphocyte function-associated antigen-1 (LFA-1).^{505,513,514} Natural killer T cells are also present.⁵¹⁵ Fibronectin is expressed in dermal vessels in positive patch test reactions; it may contribute to the recruitment of leukocytes to the site.⁵⁰² Lymphocytes liberate various cytokines in the affected area of skin,⁴⁹⁵ including IL-1 α , IL-1 β , IL-2, IL-4, IL-6, IFN- γ , and TNF- α ,^{198,199,467} leading to a further influx of inflammatory cells, particularly nonsensitized lymphocytes and some eosinophils. These cytokines trigger the release of secondary chemokines such as CCL20 and CXCL8 that further contribute to the trafficking of immune cells to the affected site.⁵¹⁶ The role of IL-12, produced by keratinocytes subject to stimulation with allergens, needs clarification in further studies.⁵¹⁷ Basophils may play a role in a very limited group of circumstances.^{500,518} Epidermal proliferation is also stimulated.⁵¹⁹ The actual pathogenesis of the spongiotic reaction still requires elucidation, but it may be due to a reduction in keratinocyte membrane E-cadherin with retention of desmosomal cadherins.⁵²⁰ Hypersensitivity to an allergen may persist for prolonged periods, although in a proportion of cases it subsides or disappears with time.⁵²¹

A systematic review of the treatment of contact dermatitis published in 2005 pointed out the effectiveness of potent or moderately potent steroids in the treatment of allergic contact dermatitis.²⁰⁵ The review suggested that the use of nonsteroid medications to treat allergic contact dermatitis needs closer examination.²⁰⁵ Rhus dermatitis can be prevented by a skin protectant or quaternium 18 bentonite (organoclay).²⁰⁵ Diethylenetriamine pentaacetic acid (chelator) cream prevents nickel, chrome, and copper dermatitis.²⁰⁵ The topical application of antioxidants in guinea pigs had some beneficial effect in reducing the sensitization to the experimental allergen.⁵²² Tacrolimus ointment has been used successfully to treat the eczematous condition known as 'jogger's nipples' (discussed previously).²³⁵ There has been only limited success with attempts to improve allergic contact dermatitis by dietary manipulation.⁵²³

Histopathology^{218,219} and Differential Diagnosis

Allergic contact dermatitis is characterized in the very early stages by spongiotic reaction, which is most marked in the lower epidermis. This is followed by the formation of spongiotic vesicles at different horizontal and vertical levels of the epidermis. This often has a very ordered

Figure 5.15 Allergic contact dermatitis. (A) There is spongiotic vesiculation. (B) Another case due to an allergic contact reaction to a plant in a florist. (H&E)

pattern (Figs. 5.15 and 5.16). When present, it allows a distinction to be made from nummular dermatitis, which may, at times, closely mimic allergic contact dermatitis histopathologically (see later). Vertical spongiosis, in which keratinocytes are oriented, and somewhat elongated, in a vertical plane is sometimes seen, but it can also be seen in other spongiotic disorders, such as drug reactions.

The upper dermis contains a mild to moderately heavy infiltrate of lymphocytes, macrophages, and Langerhans cells, with accentuation around the superficial plexus. Multinucleate dendritic–fibrohistiocytic cells are present in the upper dermis.⁵²⁴ Eosinophils are usually present, but in some cases they are present only in small numbers.⁵²⁵ There is exocytosis of lymphocytes and sometimes eosinophils. Eosinophil exocytosis is fairly characteristic of allergic contact dermatitis or a drug reaction. It can also occur in conditions characterized by eosinophilic spongiosis, which is an uncommon pattern in allergic contact dermatitis despite the finding of Wildemore *et al.*⁵²⁴ In contrast, exocytosis of eosinophils is uncommon in nummular dermatitis, although exocytosis of lymphocytes and occasional neutrophils is characteristic.

In lesions that persist, scale crust and epidermal hyperplasia develop and the dermal inflammatory cell infiltrate becomes denser. Chronic lesions may show little spongiosis but prominent epidermal hyperplasia of psoriasiform type.⁵²⁵ Mild fibrosis may develop in the papillary dermis.

Purpuric	
Pustular	
Systemic	
Urostomy-associated	
Urticarial	

Marker studies have shown that the lymphocytes are predominantly helper T cells with CD4 (Leu 3) positivity.⁵²⁶ The cells are often positive for Leu 8 and 9, markers that are uncommon in the lymphocytes in mycosis fungoides.⁵²⁶ The CD1a stain shows an increased number of Langerhans cells in the epidermis.⁵²⁷

Special variants of allergic contact dermatitis

There are several histologically distinct variants of contact dermatitis, some of which may involve an irritant rather than an allergic mechanism. Urticarial (see p. 228) and systemic contact (see p. 129) variants are discussed elsewhere. The status of the erythema multiforme-like pattern^{254,255} and a personally studied lichenoid reaction resulting from contact with chemicals in the wine industry is uncertain. The various types of contact dermatitis are shown in Table 5.4.

Pustular contact dermatitis shows exocytosis of neutrophils and the formation of subcorneal pustules.²⁴⁹ Neutrophilic spongiosis is sometimes present. Contact with cement may produce this pattern.

Figure 5.17 Allergic contact dermatitis with prominent edema of the papillary dermis as can be seen in dermal contact dermatitis. Certain specific contactants are usually associated with this pattern (see text). It also resembles the reaction seen in autosensitization. (H&E)

Purpuric contact dermatitis, from contact with textile dyes and resins (discussed previously), usually shows a mild lymphocytic vasculitis with red cell extravasation.²⁵⁷ With time, many cases go on to resemble one of the pigmented purpuric dermatoses (see p. 263) with the accumulation of hemosiderin in the upper dermis. In one case of acute purpuric dermatitis from contact with *Agave americana*, a leukocytoclastic vasculitis was present.⁵²⁸

Dermal contact dermatitis, another special variant of allergic contact reaction, has been poorly documented. Mild edema of the papillary dermis can be seen in many cases of the usual type of allergic contact dermatitis, but more pronounced edema may result from exposure to topical neomycin and to zinc and nickel salts. Such cases are called dermal contact dermatitis (Fig. 5.17). Autoeczematization (see p. 127) produces a similar pattern.

Photoallergic contact dermatitis is considered with the photosensitivity disorders (see Chapter 21). The histopathological changes may resemble those seen in allergic contact dermatitis. In cases of some months' duration, there is often telangiectasia of superficial vessels, increased and more deeply extending elastotic fibers, deep perivascular extension of the infiltrate, and stellate cells in the upper one-third of the dermis.

Granulomatous contact dermatitis refers to the presence of granulomas in the dermis resulting from a contactant. Sarcoidal granulomas have been found at the sites of ear piercing with gold earrings.²⁵² Dermal granulomas have resulted from the use of propolis, a resinous beehive product used in folk medicine.⁵²⁹ In the papular lesions that result from penetration of the allergen into the dermis in 'bindii' (*Soliva pterosperma*) dermatitis, there is a mixed dermal infiltrate with some foreign body giant cells.^{530,531} Marked edema of the papillary dermis is usually present, and draining sinuses may form.⁵³⁰

Lymphomatoid contact dermatitis is a poorly understood variant of allergic contact dermatitis in which the histological appearances may simulate cutaneous T-cell lymphoma.⁵³²⁻⁵³⁴ There is a heavy infiltrate of lymphocytes in the upper dermis in a so-called 'T-cell pattern' of distribution. Most of the reported cases have resulted from contact with chemicals or metals, such as nickel or gold.⁵³⁵⁻⁵³⁷ Other substances include baby wipes,⁵³⁸ paraphenylenediamine (by proxy),⁵³⁹ and textile dyes.⁵⁴⁰ The author has seen a recurrent case (Fig. 5.18), with a heavy superficial dermal infiltrate, that resulted from contact with Noogoora burr (*Xanthium occidentale*). Drugs have occasionally been implicated.⁵⁴¹ This latter case has since progressed

Figure 5.18 (A) Lymphomatoid contact dermatitis. (B) A dense infiltrate of lymphocytes, some mildly atypical, fills the upper dermis. The eruption developed on several occasions after contact with Noogoora burr. (H&E)

to T-cell prolymphocytic leukemia, throwing into doubt the original diagnosis.⁵⁴²

Leukodermic contact dermatitis is characterized by hypopigmentation occurring at sites of allergic contact dermatitis, as a consequence of postinflammatory melanin incontinence. It results, uncommonly, from the destruction of melanocytes or from a reduction in melanin synthesis. Betel chewing and contact with lubricants can rarely produce a vitiligo-like leukoderma as a consequence of melanocyte destruction.^{253,429} This is strictly an irritant rather than an allergic contact mechanism.

Follicular contact dermatitis has been reported following contact with formaldehyde and polyoxyethylene lauryl ether (used in cosmetics).⁵⁴³ The papules show follicular spongiosis.

Ichthyosiform contact dermatitis has been reported following the use of cetrimide. It is regarded as an acquired form of ichthyosis.

PROTEIN CONTACT DERMATITIS

Protein contact dermatitis usually presents as a chronic eczema with episodic acute exacerbations a few minutes after contact with the offending agent.⁵⁴⁴ The lesions are usually confined to the hands and forearms because occupational allergens are usually involved. Patch

testing is usually negative when read at 48 hours. Approximately 50% of those affected are atopic.

It appears that a combined type I and type IV immunological reaction is present. The causative 'protein' is a fruit, vegetable, plant, animal protein, grain, or enzyme.⁵⁴⁴⁻⁵⁴⁹ In a series of 27 patients with protein contact dermatitis, the substances most frequently responsible were fish, latex, potato, chicken, and flour.⁵⁵⁰ Responsible IgE-reactive proteins have been identified in wheat; they include a 27-kDa allergen, peroxidase, and purple acid phosphatase.⁵⁵¹

Histopathology

No distinguishing histological features have been recorded for this variant of contact dermatitis. There may be more edema of the papillary dermis than in allergic contact dermatitis.

NUMMULAR DERMATITIS

Nummular dermatitis (nummular eczema) commences with tiny papules and papulovesicles that become confluent and group themselves into coin-shaped patches that may be single or multiple.^{552,553} The surface is usually weeping or crusted, and the margins are flat. Central clearing may occur. Sites of predilection include the dorsum of the hands, the extensor surface of the forearms, the lower part of the legs, the outer aspect of the thighs, and the posterior aspect of the trunk.⁵⁵³ The course is usually chronic with remissions and exacerbations.^{552,554}

The etiology is unknown, but numerous factors have been implicated throughout the years, often with very little basis. External irritants, cold, dry weather, and a source of infection are factors that may aggravate nummular dermatitis.^{554,555} In one series, all the cases were said to be related to varicose veins and/or edema of the legs, suggesting stasis with autoeczematization as an etiological factor.⁵⁵⁶ Several drugs, such as methyl dopa, latanoprost eye drops,⁵⁵⁷ gold and antimycobacterial drugs in combination, and IFN- α -2b in combination with ribavirin,⁵⁵⁸ appear to provoke nummular eczema.⁵⁵⁹ Mercury in dental fillings has also been implicated.⁵⁶⁰ The role of bacteria in the exacerbation of nummular dermatitis is unclear, despite the fact that superantigen-producing *Staphylococcus aureus* can be found in the lesions.⁵⁶¹ There is no evidence for an atopic basis, as once thought.^{552,553,562} An association with allergic contact dermatitis has been shown in several studies,^{563,564} with the leading allergens being nickel sulfate, potassium dichromate, and cobalt chloride.⁵⁶⁴

Treatment of nummular dermatitis

Little has been written recently on the treatment of nummular dermatitis. In one study, hydration (soaking) for 20 minutes before bedtime followed by the application of corticosteroid ointment to wet skin produced good results.⁵⁶⁵ Methotrexate has been used to treat pediatric nummular dermatitis.⁵⁶⁶

Histopathology^{553,556,567}

The appearances vary with the chronicity and activity of the lesion. In early lesions, there is epidermal spongiosis and sometimes spongiotic vesiculation associated with some acanthosis and exocytosis of inflammatory cells, including lymphocytes and occasional neutrophils. The spongiotic vesicles sometimes contain inflammatory cells,⁵⁵⁶ simulating Pautrier microabscesses. There is progressive psoriasiform epidermal hyperplasia, but this is not always as uniform as in allergic contact dermatitis (discussed previously), which otherwise closely mimics nummular dermatitis. Scale crust often forms above this thickened epidermis. Using the PGP 9.5 stain, there is actually reduced intraepidermal nerve fiber density in nummular dermatitis lesions.⁵⁶⁸ There is a superficial perivascular infiltrate in the dermis composed of lymphocytes, some eosinophils, and occasional neutrophils and plasma

cells. Nummular dermatitis often has an 'untidy appearance' microscopically (Fig. 5.19).

Progressive rubbing and scratching of individual lesions lead to ulceration or the superimposed changes of lichen simplex chronicus.

SULZBERGER–GARBE SYNDROME

A rare entity, of doubtful status, Sulzberger–Garbe syndrome is also known as 'the distinctive exudative discoid and lichenoid chronic dermatosis of Sulzberger and Garbe'.^{569,570} 'Oid-oid disease' has also been used as a designation in the past. It is regarded by some as a variant of nummular dermatitis,⁵⁶⁷ although there are clinical differences. These include larger lesions, intense pruritus, a high prevalence of penile and facial lesions, and a predilection for Jewish males.⁵⁷¹

Histopathology^{567,571}

The histological changes are usually indistinguishable from those of nummular dermatitis. Scattered apoptotic keratinocytes are usually present in the basal layer. Dilatation of superficial vessels with endothelial swelling and perivascular edema have been regarded as characteristic features,⁵⁶⁹ although these are not universally accepted.⁵⁶⁷ If this disease is a variant of nummular dermatitis, it follows that apoptotic keratinocytes are also an acceptable finding in nummular dermatitis.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a chronic dermatosis of disputed histogenesis. It has a prevalence of 1–3% in the general population.^{572,573} It consists of erythematous, scaling papules and plaques, sometimes with a greasy yellow appearance, with a characteristic distribution on the scalp, ears, eyebrows, eyelid margins, and nasolabial area – the so-called 'seborrheic areas'.^{572,574} Less commonly, it may involve other hair-bearing areas of the body, particularly the flexures and pectoral region. Males are more commonly affected.⁵⁷² Seborrheic dermatitis is not usually seen until after puberty; the exact nosological position of cases reported in infancy (infantile seborrheic eczema) is uncertain,⁵⁷⁵ and their occurrence may represent another variant of the atopic tendency.⁵⁷⁶⁻⁵⁸⁰ The prevalence of seborrheic dermatitis was 10% in an Australian study of preschool children. The incidence was highest in the first 3 months of life, decreasing rapidly by the age of 1 year.⁵⁸¹

Seborrheic dermatitis is one of the most common cutaneous manifestations of AIDS, affecting 20–80% of patients.⁵⁸²⁻⁵⁸⁴ In these circumstances, it is often quite severe and atypical in distribution. It has been reported in association with alopecia following combination antiretroviral therapy.⁵⁸⁵ Seborrheic dermatitis is also seen with increased frequency in association with a number of medical disorders, including Parkinson's disease,⁵⁸⁶ epilepsy, congestive heart failure, obesity, chronic alcoholism, Leiner's disease (exfoliative dermatitis of infancy), and zinc deficiency.^{574,582} It has been reported after decompression of a Chiari I malformation; its distribution was unilateral.⁵⁸⁷ A seborrheic dermatitis-like rash that evolved into erythroderma has been reported as a paraneoplastic phenomenon.⁵⁸⁸ The high prevalence of seborrheic dermatitis in mountain guides (16%) may be the result of UV-induced immunosuppression from the occupational sun exposure.⁵⁸⁹ Seborrheic dermatitis may occur as a reaction to arsenic, gold, chlorpromazine, methyl dopa,⁵⁷⁴ cimetidine,⁵⁹⁰ and IL-2.⁵⁹¹

Pityriasis amiantacea

Pityriasis amiantacea consists of asbestos-like sticky scales, which bind down tufts of hair, involving localized areas of the scalp.⁵⁹²⁻⁵⁹⁴ Scarring alopecia is a rare complication.⁵⁹⁵ Seborrheic dermatitis is often present, although it is uncertain whether the two conditions are related.⁵⁹³

Figure 5.19 (A) Nummular dermatitis. (B) There is spongiosis, irregular acanthosis, and exocytosis of inflammatory cells. **(C)** Often, nummular dermatitis has an 'untidy' appearance. **(D)** A chronic case with superimposed lichen simplex chronicus. (H&E)

Pityriasis amiantacea is best regarded as a particular reaction pattern of the scalp to various inflammatory scalp diseases, particularly seborrheic dermatitis and psoriasis.⁵⁹⁶ A case has been reported of pityriasis amiantacea complicating psoriasis as a paradoxical eruption to TNF- α therapy.⁵⁹⁷

Dandruff

Dandruff is an extremely common affliction of the scalp; its presence can lead to loss of self-esteem and a negative social image.⁵⁹⁸ Dandruff

has been regarded as a mild expression of seborrheic dermatitis by some and as a completely separate disorder by others.^{572,599,600} The term is sometimes used for any flaking of the scalp, regardless of origin. A resurgence in interest in the role of *Malassezia* yeasts in the development of both seborrheic dermatitis and dandruff has led to the view that these two conditions are differing severity manifestations of the same condition.^{200,598,601} *Malassezia globosa* and *M. restricta* are the species most closely related to both dandruff and seborrheic dermatitis.⁵⁹⁸ Molecular studies have shown an altered balance between bacteria and fungi in patients with dandruff; in dandruff,

there is a higher incidence of *M. restricta* and *Staphylococcus epidermidis* and a lower incidence of *Propionibacterium acnes* compared to controls.⁶⁰²

Pathogenesis of seborrheic dermatitis

Traditionally, seborrheic dermatitis has been regarded as a dysfunction of sebaceous gland activity, often associated with an oily complexion. This view was supported by its localization to the 'seborrheic areas' of the body. A more recent study has shown, however, that the sebum excretion rate is not increased in patients with seborrheic dermatitis.⁶⁰³ The role of *Malassezia* sp. (*Pityrosporum*) in the etiology is also controversial.^{604–606} This organism is usually quantitatively increased in both seborrheic dermatitis and dandruff, but there is dispute about whether this is causal or a secondary event related to the increased keratin scale.^{607–610} There has been a recent resurgence of interest in the role of this organism in the pathogenesis of seborrheic dermatitis.⁶¹¹ Its role in HIV-related cases is doubted,⁶¹² no quantitative differences are usually observed in the number or distribution of yeasts in HIV-related and non-HIV-related seborrheic dermatitis,^{610,613} although there is a higher percentage of positive cultures for these organisms among immunocompromised individuals.⁶¹³ There is evidence favoring an abnormal immune response to *Malassezia furfur* and possibly other organisms, although this has been refuted.^{614–618} Other possible explanations include the production of an inflammatory mediator or alterations in lipase activity by *Malassezia*.⁶¹⁷ *Malassezia furfur* seems to play no role in the pathogenesis of the infantile form – further evidence that it may be a different disease.⁶¹⁹ A reclassification of the various species of *Malassezia* took place some years ago (see p. 695). Using the new classification, it appears that *M. globosa* and *M. restricta* are most closely related to seborrheic dermatitis, although other species (which are the most culturally robust) have also been isolated.^{598,620} Using DNA-based detection methods, *M. globosa* and *M. restricta* were the usual species isolated.⁵⁹⁸

Seborrheic dermatitis can be treated with keratolytic agents – including selenium sulfide, tar products, lithium succinate ointment, benzoyl peroxide, and propylene glycol⁶¹¹ – and anti-inflammatory products such as topical corticosteroids.⁶²¹ Specific antifungal agents include zinc pyrithione, the azoles, allylamines,⁶¹¹ and ciclopirox olamine, which is used as a shampoo or cream.⁶¹¹ Pimecrolimus cream 1% has been used successfully to treat moderate to severe facial seborrheic dermatitis.⁶²¹ Mild to moderate disease has been successfully treated with Sebclair®, a steroid-free cream containing multiple active ingredients.⁶²² A novel topical therapy employing toll-like receptors⁶²³ has been shown to produce a lower relapse rate for patients with seborrheic dermatitis compared to controls.⁶²³

Histopathology^{624,625}

The changes are those of an acute, subacute, or chronic spongiotic dermatitis depending on the age of the lesion biopsied (Fig. 5.20). In acute lesions, there is focal, usually mild, spongiosis with overlying scale crust containing a few neutrophils; the crust is often centered on a follicle. The papillary dermis is mildly edematous; the blood vessels in the superficial vascular plexus are dilated, and there is a mild superficial perivascular infiltrate of lymphocytes, histiocytes, and occasional neutrophils.⁶²⁶ There is some exocytosis of inflammatory cells, but this is not as prominent as it is in nummular dermatitis.

In *subacute lesions*, there is also psoriasiform hyperplasia, initially slight, with mild spongiosis and the other changes already mentioned. Numerous yeast-like organisms can usually be found in the surface keratin.

Chronic lesions show more pronounced psoriasiform hyperplasia and only minimal spongiosis. Sometimes the differentiation from psor-

Figure 5.20 Seborrheic dermatitis. (A) Spongiosis is not a feature in this biopsy. There is psoriasiform hyperplasia of the epidermis and focal parakeratosis. (B) Spongiosis is quite widespread in this subacute case. (H&E)

riasis can be difficult, but the presence of scale crusts in a folliculo-centric distribution favors seborrheic dermatitis.

The seborrheic dermatitis related to AIDS shows spotty cell death of keratinocytes, increased exocytosis of leukocytes, and some plasma cells and neutrophils in the superficial dermal infiltrate.⁵⁸³

Pityriasis amiantacea

There is spongiosis of both the follicular and surface epithelium with parakeratotic scale at the follicular ostia.⁵⁹² Parakeratotic scale is layered around the outer hair shafts in an 'onion skin' arrangement.⁵⁹² Sebaceous glands are sometimes shrunk. A recent study showed hyperkeratosis, composed of both basket-woven and compressed keratin, associated with globules of plasma and containing bound-down hair shafts.⁶²⁷

Dandruff

There are no spongiotic or inflammatory changes in dandruff, but only minute foci of parakeratosis scattered within the thickened orthokeratotic scale.⁶²⁸ Electron microscopy of scalp tape strips shows that dandruff scalp possesses abnormal ultrastructure of the stratum corneum that is improved with zinc pyrithione shampoo.⁶²⁸

ATOPIC DERMATITIS

Atopic dermatitis (atopic eczema) is a chronic, pruritic, inflammatory disease of the skin that usually occurs in individuals with a personal and/or family history of atopy (asthma, allergic rhinitis, and atopic dermatitis).⁶²⁹⁻⁶³⁸ It is a common disorder with an incidence of approximately 1% or 2%,⁶³⁰ its prevalence appears to be increasing in children,⁶³⁹ particularly in the Western world, where incidences as high as 15–20% have been recorded.⁶⁴⁰⁻⁶⁵³ Onset is usually in infancy or childhood.^{632,654} It is associated with considerable morbidity and resource use.⁶⁵⁵ Insufficient attention has been given to a major cause of this morbidity – *itch*.^{656,657}

The diagnosis of atopic dermatitis is made on the basis of a constellation of major and minor clinical features.⁶⁵⁸⁻⁶⁶³ Its distinction from infantile seborrheic dermatitis is sometimes difficult.^{676,634,664-666} Major criteria for the diagnosis of atopic dermatitis include the presence of pruritus, chronicity, and a history of atopy, as well as lesions of typical morphology and flexural distribution.^{631,658} Boys are more often atopic than girls.⁶⁶⁷ In infants and young children, there is an erythematous, papulovesicular rash with erosions involving the face and extensor surfaces of the arms and legs.⁶⁶⁸ The involvement of the scalp, forehead, ear, and neck has been described as a ‘balaclava’ distribution.⁶⁶⁹ These early lesions are followed by more typical lesions involving the flexures of the extremities.⁶⁶⁹ This progresses with time to a scaly, lichenified dermatitis.⁶⁷⁰ Involvement of the hands and feet may occur at a later stage. Adult-onset atopic dermatitis is a recently introduced subgroup.⁶⁷¹ In addition to the typical lichenified/exudative lesions of the flexures, a nonflexural distribution may also occur.⁶⁷² Nummular and prurigo-like lesions may develop in adults.⁶⁴² The vulva and nipples are sometimes involved.⁶⁷³⁻⁶⁷⁵ Itchy follicular papules on the trunk are quite common in Oriental and black patients.^{676,677} A patient with linear distribution of the lesions has been reported.⁶⁷⁸ In another, there was increased severity along a line of Blaschko.⁶⁷⁹

Minor clinical features^{629,631,680} include xerosis, which may be focal or generalized, elevated IgE that is allergen specific,⁶⁸¹ interleukin-2 receptor (IL-2R),⁶⁸² eosinophil cationic protein (ECP),⁶⁸³⁻⁶⁸⁵ E-selectin⁶⁸⁶⁻⁶⁸⁹ and IgG4 in the serum,^{670,690,691} increased colonization of the skin with *Staphylococcus aureus*,⁶⁹²⁻⁶⁹⁴ a greater risk of viral and fungal infections of the skin,⁶⁹⁵ pityriasis alba,⁶⁶⁸ rippled hyperpigmentation,⁶⁹⁶ reduced numbers of melanocytic nevi,⁶⁹⁷ keratosis pilaris, cheilitis, nipple eczema, food intolerance,^{698,699} orbital darkening, white dermatographism, and an increased incidence of dermatitis of the hands, including pompholyx and irritant dermatitis.^{700,701} Although one study found an increased risk of malignancy, albeit of borderline statistical significance,⁷⁰² another study has reported a lower risk.⁷⁰³ Hypertension is also rare in adult patients with atopic eczema.⁷⁰⁴ Patients with severe disease have low basal serum cortisol levels, a finding previously attributed to the use of potent topical corticosteroids.⁷⁰⁵ The ethnic background of the patient appears to influence the phenotype and the relative incidence of the various minor clinical features in atopic dermatitis.⁷⁰⁶ There have been several cases of atopic dermatitis associated with Sjögren’s syndrome, with or without lupus erythematosus,^{707,708} associated with particularly dry skin. It was proposed that the abnormal sudomotor axon reflex in atopic individuals may have been exacerbated by this complicating autoimmune disease.⁷⁰⁸

A distinctive clinical variant of atopic dermatitis (*lichenoid atopic dermatitis*) has been reported in nearly 10% of patients presenting to one institution in the United States.⁷⁰⁹ Lesions were almost indistinguishable clinically from lichen planus but without the pathological findings of lichen planus.⁷¹⁰ All patients were heavily pigmented (Fitzpatrick skin types V and VI) persons.⁷⁰⁹ The lesions were spongiotic with mild lymphocyte exocytosis and only scattered apoptotic keratinocytes.⁷⁰⁹

Atopic dermatitis-like skin lesions (atopiform dermatitis) can be seen in a number of genodermatoses,⁶⁸¹ the most important of which is ichthyosis vulgaris.⁶⁶⁸ They also occur in the Wiskott–Aldrich syndrome,^{711,712} X-linked agammaglobulinemia,⁷¹³ ataxia–telangiectasia, IPEX syndrome,⁷¹⁴ Andogsky syndrome (atopic dermatitis with cataracts),⁷¹⁵ and in some patients with phenylketonuria.⁶⁶⁸ Atopic dermatitis is also a feature of Job’s syndrome (see p. 1134).⁷¹⁶⁻⁷¹⁸ An atopic diathesis is also found in Netherton’s syndrome (see p. 288), due to a defect in the *SPINK5* gene at 5q31–q32.⁷¹⁹ Polymorphisms in this gene have been associated with atopic dermatitis in one Japanese study.⁷¹⁹ The incidence is probably not increased in Down syndrome.⁷²⁰ Atopic dermatitis has recently been reported in association with the tricho-dento-osseous syndrome, which is due to a mutation in the *DLX3* gene on chromosome 17q21.⁷²¹

The term *atopiform dermatitis* has been used in the past for the atopic dermatitis-like eruptions associated with some genodermatoses (discussed previously). It is now being used for the ‘intrinsic’ type of atopic dermatitis, which is characterized by the absence of allergen-specific IgE.⁷²² This group has female predominance, absence of atopic diseases, later onset of the disease, and milder clinical severity; it may be a distinct disease.⁷²²

Two cases of an atopic dermatitis-like rash have been reported in psoriasis patients treated with infliximab.⁷²³ Patchy pityriasiform lichenoid eczema, characterized by scaly follicular papules forming larger plaques, is another variant of atopic dermatitis.⁷²⁴

The course of atopic dermatitis is one of remissions and exacerbations; the symptom-free periods tend to increase with age.⁶³¹ There is also a tendency toward spontaneous remission in adult life, although some studies have shown lower remission rates than previously thought.⁷²⁵ Sleep disturbance is common in patients with atopic dermatitis.⁷²⁶ Outcome studies, including the response to various treatments,⁷²⁷⁻⁷³⁵ rely on consistency in the measurement of disease activity/severity. Unfortunately, there is less consistency than is desirable between the various severity scales.⁷³⁶ The serum levels of IL-16, IL-18, IgE, and cutaneous T-cell attracting chemokine (CTACK) are a good reflection of disease severity.⁷³⁷⁻⁷⁴⁰ Some children with atopic dermatitis will develop allergic respiratory diseases later in childhood.⁷⁴¹ Positive skin-prick tests to food allergens, severe skin disease, and a high serum IgE level are risk factors for the later development of allergic respiratory disease.⁷⁴²

Pathogenesis of atopic dermatitis

Although the etiology and pathogenesis of atopic dermatitis are still unclear, evidence suggests that IgE-mediated late phase responses, as well as cytokine imbalances and cell-mediated reactions (T-lymphocyte activation), contribute in some way.⁷⁴³⁻⁷⁵⁷ Expressed more specifically, there is an expansion of the skin-homing type 2 cytokine-secreting T cells (Th2), leading to increased levels of IL-4, -10, -13, and -16 and of IgE.⁷⁵⁸⁻⁷⁶⁶ There is a corresponding decrease in IFN- γ .^{727,758,759,767} There is a strong expression of the suppressor of cytokine signaling 3 (SOCS3) in the skin of patients with atopic dermatitis.⁷⁶⁸ It may mediate a Th2 regulatory response through negative regulation of Th1 pathways.⁷³⁵ The expression of CD43 is increased.⁷⁶⁹ Keratinocytes are a source of the chemokines that result in the influx of both Th2 cells and eosinophils.⁷⁷⁰ As the disease progresses, there is a switch from Th2 responses to a Th1 profile.

The IgE-mediated reactions may be to ingested food^{670,771-774} or to inhaled or contactant aeroallergens⁷⁷⁵⁻⁷⁷⁷ such as human dander,⁷⁷⁸ environmental tobacco smoke,⁷⁷⁹ grass pollens,⁷⁸⁰ disperse clothing dyes,⁷⁸¹ and house dust and other mites.⁷⁸²⁻⁷⁹³ Dust mite elimination was thought to have a beneficial effect on the control of atopic dermatitis,^{789,794} but recent studies have failed to confirm any benefit of dust mite elimination.⁷⁹⁵ A 2006 systematic review of factors causing worsening of ‘eczema’ found evidence that certain foods (particularly

eggs⁷⁹⁶), house dust mite, stress,^{797–800} and seasonal factors were implicated in certain subgroups.⁸⁰¹ Another review of etiological factors in atopic dermatitis found an inverse relationship between atopic dermatitis and endotoxins, day care from a very young age, and animal exposure.⁸⁰² There was a positive association between atopic dermatitis and infections in early life, measles vaccination, and antibiotic use.^{802,803} There are significant associations with the presence of dampness in the home, the use of radiators to heat the child's bedroom, the use of synthetic pillows,⁸⁰⁴ and a privileged socioeconomic status.^{805,806} Breast-feeding reduces the incidence of atopic dermatitis during childhood in children with a family history of atopy.⁸⁰⁷ This effect is negligible in children without first-order atopic relatives.⁸⁰⁷ Recent studies have failed to demonstrate any clear relationship between this disease and indoor aeroallergens in early life.⁷⁹⁵ There is no association with furry pets.⁸⁰⁸ Nevertheless, endotoxin exposure is not only important during the maturation of the immune system early in life but also may influence the development of an allergic disease, such as asthma and atopic dermatitis, in a predisposed individual.⁸⁰⁹ Antigens of *Staphylococcus aureus* and other bacteria, as well as the yeast *Malassezia*,^{810–813} have been considered as possible stimulants of the IgE response.^{758,814–817} Defects in toll-like receptor 2 (TLR2) signaling may be a cause of the reduced ability to clear *Staphylococcus aureus* from the skin.⁸¹⁸ This is because reduced TLR2 expression correlates with epidermal tight junction defects and reduced barrier function, with increased proneness to *Staphylococcus aureus* infections and increased transepidermal water loss. There is evidence that TLR2 agonists can help enhance skin barrier function and perhaps reverse these effects.⁸¹⁹ Approximately 10% of patients have normal serum IgE levels (non-allergic or intrinsic atopic dermatitis).⁸²⁰ Studies of this group have shown a lack of IL-13-induced B-cell activation, resulting in decreased IgE production.⁸²¹

Cellular changes in atopic dermatitis, in addition to the increase in Th2 lymphocytes, include an increase in inflammatory dendritic cells in the epidermis (either altered Langerhans cells or cells derived from the CD34 subset of dendritic cells)⁶³⁶ and dermis⁸²² and an increased life span of eosinophils.⁶³⁶ Eosinophils are increased in the subgroup of patients with so-called extrinsic disease, in which IgE levels are increased.⁸²³ Langerhans cells appear to be hyperstimulatory.^{749,824–826} Langerhans cells and inflammatory dendritic cells express the high-affinity receptor for IgE (FcεRI).⁸²⁷ Such cells are not found in normal skin. Skin fibroblasts produce increased amounts of inducible protein-10 (IP-10), although the significance of this finding is currently unknown.⁸²⁸

Changes in mediators and receptors occur,⁸²⁹ but there have been conflicting results depending on the model used and the method of measurement. No single cytokine can be said to have a pivotal role. Increased expression of Fc receptors for IgG⁸³⁰ and of integrins is present.⁶⁸⁸ Serotonin,⁸³¹ leukotriene E4,⁸³² nerve growth factor and substance P,^{798,833,834} and matrix metalloproteinase-9 levels are all increased. Prostaglandins may not be as important as previously thought.⁸³⁵

Patients with atopic dermatitis have a reduced itch threshold⁸³⁶ and greater skin 'irritancy'.^{837,838} It appears that mast cell mediators other than histamine are involved in the pruritus.^{839,840} These findings may be explained by a study that found that the sensitization for itch in atopic dermatitis may be in the spinal cord rather than in primary afferent neurons.⁸⁴¹ This has implications for treatment and suggests that anti-pruritic therapy should also focus on these central mechanisms of pruritus.⁸⁴¹

Genetic factors also appear to be involved in the pathogenesis of atopic dermatitis in some way.^{842–844} This is confirmed by the frequent presence of a family history of atopy and the high concordance in twins.^{842,845–847} There is some allelic association with chromosomes 11q13, 13q12–q14, and 5q31–q33.^{848,849} Interestingly, the gene for the β subunit of FcγRI, the high-affinity receptor for IgE, has been localized to chromosome 11q12–q13.⁷⁵⁴ Polymorphisms in the IL-13 (IL-13) gene are not associated with atopic dermatitis. A single nucleotide polymorphism in the *GATA3* gene is associated with atopic

dermatitis.⁸⁵⁰ Another candidate gene on chromosome 16p11–p12 is associated with the *IL-4R* gene.⁸⁵¹ Polymorphisms within the *CTLA4* gene at 2q33 have been associated with early onset disease.⁸⁵² It encodes the inhibitory CTLA4 receptor, an important regulator of T cells and cytokine secretion.⁸⁵² Single-nucleotide polymorphisms in the eotaxin gene have been found in patients with the extrinsic form of atopic dermatitis.⁸⁵³ Nevertheless, cytokine gene polymorphisms may be markers of inflammatory skin diseases in general rather than specific markers of atopic dermatitis.^{854–856}

Finally, impaired skin barrier function plays a key role in the development of atopic disease.^{857–860} An early study found a reduction in ceramide in the stratum corneum,⁸⁶¹ but in 2006 two loss-of-function variants in the gene encoding the epidermal barrier protein filaggrin (*FLG*) at 1q21 were reported.^{859,862} Other studies have since confirmed this finding.^{863,864} These genetic variants are found in approximately 9% of people of European origin. Filaggrin (*FLG*) gene mutations appear to be an independent risk factor for irritant contact dermatitis, but when concurrent with atopic dermatitis, they actually further increase the risk of this form of dermatitis.⁸⁶⁵ There is also a significant association with asthma occurring in the context of atopic dermatitis.⁸⁵⁹

The management of patients with atopic dermatitis involves avoidance of provocation factors, the selective use of antimicrobial therapy, and the use of emollients⁸⁶⁶ and topical corticosteroids.⁶³⁸ Other therapies include antihistamines,⁸⁶⁷ topical calcineurin inhibitors,^{868,869} infliximab monotherapy,⁸⁷⁰ efalizumab,⁸⁷¹ alefacept,⁸⁷² high-dose intravenous immunoglobulin,⁸⁷³ leflunomide, recombinant IFN-γ, adjuvant UVA therapy, heliotherapy,⁸⁷⁴ hypnotherapy, probiotics, pulsed-dye laser for localized areas of chronic atopic dermatitis,⁸⁷⁵ and the peroxisome proliferator-activated receptor ligand rosiglitazone as adjunctive therapy in the treatment of severe disease.⁸⁷⁶

Histopathology^{630,877–880}

Atopic dermatitis presents the typical spectrum of acute, subacute, and chronic phases as seen in some other spongiotic (eczematous) processes.⁸⁷⁹ As such, the biopsy appearances may be indistinguishable from those seen in nummular dermatitis and allergic contact dermatitis. Subtle features (listed later) may sometimes allow the diagnosis to be made on biopsy, although most often the dermatopathologist is restricted to describing the findings as 'consistent with atopic dermatitis'.

Acute lesions show spongiosis and some spongiotic vesiculation,⁸⁸⁰ even though some authorities deny the presence of spongiosis in atopic dermatitis. There is usually some intracellular edema as well, leading to pallor of the cells in the lower epidermis.⁸⁷⁸ Exocytosis of lymphocytes is usually present, although it is never a prominent feature. There is a perivascular infiltrate of lymphocytes and macrophages around vessels of the superficial plexus, but there is no significant increase in mast cells or basophils in acute lesions.⁸⁷⁸ The mast cells present are in different stages of degranulation, indicating activation of these cells.⁷⁵¹ Occasional eosinophils may be present.

Subacute lesions show irregular acanthosis of the epidermis with eventual psoriasiform hyperplasia. With increasing chronicity of the lesion, the changes of rubbing and scratching become more obvious and the spongiosis less so.

Chronic lesions show hyperkeratosis, moderate to marked psoriasiform hyperplasia, and variable but usually only mild spongiosis. Mast cells are now significantly increased in the superficial perivascular infiltrate.^{877,878} Eosinophils are also present.⁸⁸¹ Small vessels appear prominent due to an increase in their number and a thickening of their walls that involves both endothelial cells and the basement membrane.⁸⁷⁸ Demyelination, focal vacuolation, and fibrosis of cutaneous nerves are also observed.^{877,878} Epidermal keratinocytes produce increased amounts of neurotrophin-4 in the chronic pruriginous lesions of atopic dermatitis. It may be responsible for the nerve hypertrophy

that is sometimes seen.⁸⁸² Langerhans cells are increased in both the epidermis and the dermis.^{883–885} With further lichenification of the lesions, there is prominent hyperkeratosis and some vertical streaking of collagen in the papillary dermis – the changes recognized as lichen simplex chronicus. Collagen types I and III increase in the dermis following PUVA therapy.⁸⁸⁶ Lichenified lesions have an increased number of mast cells in the dermis.⁸⁸⁷

If dry skin is biopsied in patients with atopic dermatitis, there is usually focal parakeratosis, mild spongiosis, and a mild perivascular infiltrate involving the superficial plexus.⁸⁸⁸ There is focal hypergranulosis in those with dry skin alone⁸⁸⁹ but a reduced granular layer in those who have concurrent ichthyosis vulgaris.⁸⁸⁸

The nature of the 'angiohistiocytoid papules' reported in two patients with atopic dermatitis from Japan is unclear.⁸⁹⁰ They consisted of increased vascularity surrounded by histiocytoid cells that expressed factor XIIIa but not CD68.⁸⁹⁰

The rippled hyperpigmentation ('dirty neck') seen in approximately 2% of atopic individuals results from melanin incontinence (see p. 343). Amyloid-like material has been seen on electron microscopy, but not on light microscopy, using the Congo red stain.⁸⁹¹

Infective dermatitis, a recently delineated entity in children and young adults, has similar clinical and histopathological features (see p. 744). It appears to be caused by infection with human T-lymphotropic virus type 1 (HTLV-1).

Differential diagnosis

As previously mentioned, there are several morphological features that, if present, favor the diagnosis of atopic dermatitis over the other spongiotic dermatitides that it closely resembles. The assessment of these features is somewhat subjective and, in some, it involves the use of techniques that are not routine. Features favoring the diagnosis of atopic dermatitis include prominence of small blood vessels in the papillary dermis, atrophy of sebaceous glands (this change is usually present only in those who have concomitant ichthyosis vulgaris),⁸⁸⁸ and an increase in epidermal volume without psoriasiform folding of the dermoepidermal interface (Fig. 5.21).⁸⁹² This latter change is a useful clue to the diagnosis of atopic dermatitis. Eosinophils and basophils are usually more prominent in the infiltrate of allergic contact dermatitis than in atopic dermatitis. Despite this relative paucity of eosinophils in atopic dermatitis, eosinophil major basic protein has been reported in the upper dermis in a fibrillar pattern.⁸⁹³ It may also be found at other levels of the dermis.⁸⁹⁴ The diagnostic value of this feature requires further study, as do the findings of perivascular IgE⁸⁹⁵ and intercellular epidermal staining for IgE, HLA-DR, and CD1a in atopic dermatitis.⁸⁹⁶ This also applies to the finding of a predominantly T-helper-cell (CD4⁺) infiltrate in atopic dermatitis^{884,885,897} and a T-suppressor-cell (CD8⁺) infiltrate in allergic contact dermatitis;⁸⁹⁵ the latter finding does not accord with the results of other studies.⁵²⁶ In fact, a recent study found that although CD4⁺ cells are indeed present in atopic dermatitis skin (of Th2 type, as expected), there are actually increased numbers of CD8⁺ T cells, both in the epidermis and in the dermis of atopic skin lesions; these cells produce IL-13, IFN- γ , and IL-22.⁸⁹⁸

PAPULAR DERMATITIS

Papular dermatitis (subacute prurigo, 'itchy red bump' disease) presents as a pruritic papular eruption with superimposed secondary changes due to excoriation.⁸⁹⁹ The lesions tend to be symmetrically distributed on the trunk, the extensor surfaces of the extremities, face, neck, and buttocks.

The etiology is unknown, although some patients have an atopic background. The earlier view that this may be a form of *Cheyletiella* dermatitis is no longer tenable (see p. 774). A variant of linear IgA

Figure 5.21 (A) Atopic dermatitis. (B) There is an increase in epidermal volume that is associated with only partial psoriasiform folding. Focal parakeratosis is also present. (H&E)

bullous dermatosis clinically resembling papular dermatitis (subacute prurigo) has been described.⁹⁰⁰ There is increased expression of IL-4, -17, -22, and -31 in lesions diagnosed as subacute and chronic prurigo.⁹⁰¹

Histopathology

There is variable epidermal spongiosis and focal parakeratosis. Excoriation and changes of rubbing and scratching are usually present. There is a mild superficial perivascular infiltrate of lymphocytes with a few eosinophils. These changes are not diagnostically specific, being present in other endogenous dermatitides. The inflammatory infiltrate is composed mainly of T lymphocytes, particularly CD8⁺ lymphocytes, CD15⁺ neutrophils, and CD68⁺ macrophages.⁹⁰²

POMPHOLYX

Pompholyx (acral vesicular dermatitis, dyshidrotic eczema) is a common, recurrent, vesicular eruption of the palms and soles that is one of several clinical expressions of so-called 'chronic hand dermatitis'.^{903,904} It consists of deep-seated vesicles, often with a burning or itching sensation, most commonly involving the palms, volar aspects

of the fingers, and sometimes the sides of the fingers.⁹⁰⁴ In one study, lesions were palmar in 70%, plantar in 10%, and palmoplantar in 20% of patients.⁹⁰⁵ The mean age of patients in this series was 35 years (range, 7–72 years), and there was a slight female predominance.⁹⁰⁵ Excluded from this series were cases with erythema associated with the vesicles (thus eliminating contact eczemas) and cases that did not exhibit a cyclic pattern of recurrent short-term attacks.^{206,905} Lesions usually resolve after several weeks, leading to localized areas of desquamation.

The term ‘dyshidrotic eczema’ was introduced because of a mistaken belief that the pathogenesis of this condition involved hypersecretion of sweat and its retention in the acrosyringia.⁹⁰⁶ The term should be avoided. Pompholyx is a spongiotic dermatitis, the expression of which is modified by the thickened stratum corneum of palmar and plantar skin that reduces the possibility of rupture of the vesicles. Episodes may be precipitated by infections, including dermatophyte infections at other sites (‘id reaction’; p. 127),⁹⁰⁷ contact sensitivity to various allergens such as medicaments, shower gel, food (paprika, orange juice, and crustaceans), mercury in amalgam fillings,⁵⁶⁰ nickel,⁹⁰⁷ chromium, and emotional stress.⁹⁰⁸ Smoking is a rare triggering factor,⁹⁰⁵ but it may have been responsible for four cases of painful lower leg ulceration that developed in patients with pompholyx.²⁰⁷ In one series of 120 patients, 67.5% of cases were regarded as allergic contact pompholyx, with cosmetic and hygiene products as the main factor, followed by metals.⁹⁰⁵ Five patients in whom pompholyx was photoinduced have been reported.⁹⁰⁹ Approximately 15% of cases are idiopathic, but nearly all these patients are atopic.^{905,910,911}

Histopathology⁹⁰⁶

Pompholyx is characterized by spongiosis of the lower malpighian layer with subsequent confluence of the spongiotic foci to form an intraepidermal vesicle (Fig. 5.22). The expanding vesicles displace acrosyringia at the outer margin of the vesicles. There is a thick, overlying stratum corneum, characteristic of palms and soles. Other changes include a sparse, superficial perivascular infiltrate of lymphocytes with some exocytosis of these cells. Some people develop pompholyx-like vesicles that soon evolve into pustules with histopathological features of pustulosis palmaris (see p. 147). A PAS stain should always be performed on vesicular lesions of the palms and soles, particularly if there are any neutrophils within the vesicles or stratum corneum, because dermatophyte infections may mimic the lesions of pompholyx (Fig. 5.23).

Differential diagnosis

Allergic contact dermatitis of the palms and soles may also be difficult to distinguish from pompholyx. In the former condition, mild spongiosis may be present adjacent to the vesicles, and there are sometimes eosinophils in the inflammatory infiltrate. In a comparative study of the histopathologic features of palmoplantar pustulosis and pompholyx, the former featured loss of the granular cell layer, thinning of suprapapillary plates, eosinophils within pustulovesicles, tortuous capillaries, capillaries contacting the undersurface of the epidermis, and extravasated erythrocytes, whereas multiple parakeratotic foci, irregular acanthosis, and thinning of rete ridges were more typical of pompholyx.⁹¹²

UNCLASSIFIED ECZEMA

Little attention has been given in the literature to the significant number of patients who have an eczematous process that does not fit the criteria for any known type. Clinicians have usually used the term endogenous dermatitis (eczema) for these cases. Because the histologi-

Figure 5.22 Pompholyx. A unilocular vesicle is present within the epidermis. There is no spongiosis in the adjacent epidermis. (H&E)

Figure 5.23 Dermatophyte infection of the hands. There are only scattered neutrophils in the spongiotic vesicle, testimony to the necessity to keep a fungal infection in mind when the spongiotic reaction pattern is present on the hands or feet. (H&E)

cal appearances of many categories of spongiotic (eczematous) dermatitis are not characteristic of a specific disease process, particularly after treatment and secondary changes such as scratching are taken into account, dermatopathologists have usually diagnosed ‘spongiotic dermatitis’. A 2008 report from China reviewed 655 such patients with ‘unclassified eczema’.⁹¹³ The authors concluded that unclassified eczema is a common type of eczema with a very poor prognosis.⁹¹³ An accompanying editorial titled ‘Addition of Nonspecific Endogenous Eczema to the Nomenclature of Dermatitis’ stressed that this was a diagnosis of exclusion.⁹¹⁴

HYPERKERATOTIC DERMATITIS OF THE PALMS

A somewhat neglected entity, hyperkeratotic dermatitis of the palms (eczema keratoticum) is a clinical variant of chronic hand dermatitis.^{903,915} It presents as a sharply marginated, fissure-prone, hyperkeratotic dermatitis that is limited usually to the palms and occurs chiefly in middle-aged persons.⁹¹⁶ Involvement of the volar surfaces of the

fingers is quite common. Plantar lesions are rare. The cause of the condition is unknown; some cases may be related to psoriasis.⁹¹⁶

Various treatments have been used, including emollients, keratolytic agents, tar, topical corticosteroids in an ointment base combined with a keratolytic agent such as salicylic acid, or PUVA therapy.⁹¹⁶ Acitretin and etretinate have been used for refractory cases.⁹¹⁶

Histopathology

The appearances are those of a chronic spongiotic dermatitis with spongiosis and psoriasiform hyperplasia of the epidermis, although the elongation of the rete ridges is usually not as regular as in psoriasis. There is overlying compact orthokeratosis with small foci of parakeratosis. There is a moderately heavy chronic inflammatory cell infiltrate in the papillary dermis, predominantly in a perivascular location. Lymphocyte exocytosis is quite prominent in the epidermis, but there are usually no neutrophils. The amount of spongiosis allows a distinction to be made from psoriasis.

JUVENILE PLANTAR DERMATOSIS

Juvenile plantar dermatosis is a condition that affects children between the ages of 3 and 14 years.⁹¹⁷ It presents as a shiny, scaly, erythematous disorder of weight-bearing areas of the feet.⁹¹⁸ Fissuring subsequently develops. Sometimes the hands, particularly the fingertips, are also affected. Most cases improve over the years.

The etiology is uncertain, with conflicting evidence on the role of atopy and of footwear.^{919,920} **Dermatitis palmaris sicca** is a related lesion of the palms.⁹²¹

Histopathology^{918,922,923}

Juvenile plantar dermatosis shows variable parakeratosis and hypogranulosis overlying psoriasiform acanthosis. A distinctive feature is the presence of spongiosis, mild spongiotic vesiculation, vacuolization of keratinocytes, and exocytosis of lymphocytes, localized to the epidermis surrounding the acrosyringium.⁹¹⁸ Lymphocytes are present in the upper dermis around the sweat ducts at their point of entry into the acrosyringium.⁹¹⁸ Ducts and acrosyringia are not dilated.⁹²²

VEIN GRAFT DONOR-SITE DERMATITIS

A subacute spongiotic dermatitis has been recorded in several patients at the site from which a saphenous vein graft was removed.⁹²⁴ There was a sensory peripheral neuropathy in the distribution of the dermatitis. Other changes reported at donor sites include the presence of localized myxedema in Graves' disease and the formation of an indurated linear plaque resulting from cutaneous sclerosis (see p. 364). Cellulitis of the lower leg is another complication.

STASIS DERMATITIS

Stasis dermatitis (hypostatic dermatitis) is a common disorder of middle-aged and older individuals. It is a consequence of impaired venous drainage of the legs.⁹²⁵ A recent study provides evidence that venous hypertension alone can cause lower leg stasis dermatitis, without input from contact sensitization.⁹²⁶ In the early stages, there is edema of the lower one-third of the legs, which have a shiny and erythematous appearance. Subsequently, dry and scaly or crusted and weeping areas may develop.⁹²⁵ Sometimes the changes are most prominent above the medial malleoli. Affected areas become discolored, due in part to the deposition of hemosiderin in the dermis. Ulceration is a frequent complication of stasis dermatitis of long standing.⁹²⁵ Stasis dermatitis of the abdominal wall has been reported in the Budd–Chiari

Figure 5.24 Stasis dermatitis. There are mild spongiosis and a proliferation of small vessels in the papillary dermis. (H&E)

syndrome.⁹²⁷ The patches of eczema that developed in a port-wine stain of the arm were regarded as analogous to stasis dermatitis.⁹²⁸

Affected skin is unusually sensitive to contactants, and not infrequently, topical medications applied to these areas result in an eczematous reaction that can be quite widespread. This process of 'autoeczematization' is poorly understood (discussed later).

Histopathology^{925,929}

Stasis dermatitis is unlikely to be biopsied unless complications such as ulceration, allergic contact dermatitis, or basal cell carcinoma arise. In stasis dermatitis, the spongiosis is usually mild, although spongiotic vesiculation may develop if there is a superimposed contact dermatitis. Focal parakeratosis and scale crusts may also be present.

The dermal changes are usually prominent and include a proliferation of small blood vessels in the papillary dermis (Fig. 5.24). This neovascularization may lead occasionally to the formation of a discrete papule. There is variable fibrosis of the dermis that can be quite prominent in cases of long standing. Abundant hemosiderin is present throughout the dermis. It is not localized to the upper third of the dermis, as occurs in the pigmented purpuric dermatoses (see p. 264). The veins in the deep dermis and subcutis are often thick walled.

AUTOECZEMATIZATION

Autoeczematization (autosensitization) is characterized by the dissemination, often widespread and quick, of a previously localized 'eczematous' process.⁹³⁰ The term is often used with less precision to apply to other autosensitization reactions, whereby an inflammatory dermatitis develops at a site distant to the original inflammatory process or insult. The term 'id reaction' has also been applied to this latter group, which now seems less commonly used than previously.

Included in the broad concept of autosensitization/autoeczematization are the distant reactions to localized dermatophyte infections (e.g., pompholyx of the hands in response to dermatophyte infection elsewhere); to localized bacterial infections, scabies, burns, and ionizing radiation,⁹³⁰ and also to stasis dermatitis (discussed previously). Generalization of a localized cutaneous eruption has been reported following the use of systemic prednisolone.⁹³¹ The development of recalcitrant eczema in patients with lymphoma or leukemia may result from a

similar mechanism.⁹³² Some of the lesions that developed after an iguana bite were thought to represent autoeczematization.⁹³³ The superantigen id reaction, as described by Crowson and Magro (see p. 193), was regarded as an immunological response to arthropathy-associated microbial pathogens. Although mostly resembling interstitial granulomatous dermatitis, some lesions were spongiotic.

The mechanism responsible for these reactions involves an abnormal immune response to autologous skin antigens.⁹³⁴ Activated T lymphocytes appear to mediate this response.^{935,936}

Histopathology

The histopathological reactions have not been widely studied. In cases of dissemination of an originally localized process, the changes will usually mimic those seen in the initial lesions. In other instances, the generalized reaction is that of a spongiotic process of variable intensity. In the author's experience, there has often been some edema of the superficial papillary dermis with some large (presumably activated) lymphocytes in the upper dermis. These two features may also be seen in spongiotic drug reactions (see below) and dermal, systemic, and protein contact dermatitis (see p. 119). Dermal edema may also be seen in the pompholyx associated with this process of autoeczematization (see p. 125). However, when epidermal spongiosis is associated with subepidermal edema and a history of rapid generalization of an initially localized lesion, autoeczematization will usually be present (Fig. 5.25).

PAPULAR ACRODERMATITIS OF CHILDHOOD

Papular acrodermatitis of childhood (Gianotti–Crosti syndrome) is an uncommon, self-limited disease of low infectivity characterized by the triad of an erythematous papular eruption of several weeks' duration, localized to the face and limbs, mild lymphadenopathy, and acute hepatitis that is usually anicteric.^{937–939} The skin lesions are flat-topped papules 1–2 mm in diameter, which sometimes coalesce. An isomorphic response (Koebner phenomenon) is often present.⁹⁴⁰ The lesions may be mildly pruritic. Hepatitis B surface antigen is often present in the serum.^{941–943}

It is now apparent that other viral infections – particularly infection with the Epstein–Barr virus,^{944,945} coxsackievirus A16,⁹⁴⁶ parainfluenza virus, hepatitis A virus,⁹⁴⁷ hepatitis C virus,⁹⁴⁸ human immunodeficiency virus,⁹⁴⁹ cytomegalovirus,⁹⁵⁰ and herpes simplex virus type I gingivostomatitis⁹⁵¹ – are occasionally associated with a similar acral dermatitis;^{952,953} hepatitis and lymphadenopathy are not commonly present in these circumstances.^{952,953} Gianotti used the term 'papulovesicular acrorelated syndrome' for these cases.^{939,954} Although infections associated with these other viruses often pursue a longer course and may have tiny vesicular lesions, individual cases occur that closely resemble those associated with the hepatitis B virus. Accordingly, it seems best to group all these virus-related disorders under the term Gianotti–Crosti syndrome. Gianotti–Crosti syndrome has also been reported to follow several different vaccinations, including H1N1 influenza vaccination.⁹⁵⁵

In the author's experience, there is an increasing incidence of cutaneous reactions to viral and presumptive viral infections, ranging from those resembling Gianotti–Crosti syndrome at one end of the spectrum to others with histological features of mild pityriasis lichenoides. The clinical expression and distribution of these changes is somewhat variable, making the delineation of a specific clinicopathological entity a difficult task.

Histopathology⁹⁵⁶

Although the changes are not diagnostically specific, they are often sufficiently characteristic at least to suggest the diagnosis. The appearances at low magnification often suggest that three tissue reactions – lichenoid, spongiotic, and vasculitic – are simultaneously present.⁹⁵² On closer inspection, there is prominent exocytosis of mononuclear cells into the lower epidermis. This is usually associated with some basal vacuolar change, but cell death is not a conspicuous feature.⁹⁵⁷ The spongiosis is usually mild, but small spongiotic vesicles, containing a few inflammatory cells and resembling those of pityriasis rosea, may be present (discussed previously). Although most observers specifically deny the presence of a vasculitis, because of the absence of fibrin,⁹³⁷ there is always a tight perivascular infiltrate of lymphocytes associated with variable endothelial swelling. In many instances, the changes merit a diagnosis of lymphocytic vasculitis.⁹⁵² The inflammatory infiltrate not only fills the papillary dermis and extends into the epidermis but also usually involves the mid and even the lower dermis to a lesser extent. There is often some edema of the papillary dermis. Epidermal spongiosis is less prominent in cases related to the hepatitis B virus.

SPONGIOTIC DRUG REACTIONS

Spongiotic reactions to drugs occur in several different clinical and pathogenetic settings, although in some instances the precise mechanism that results in the spongiosis is unknown (Table 5.5). A delayed hypersensitivity response is usually suspected.⁹⁵⁸ The three major categories of spongiotic drug reactions are provocation of an endogenous dermatitis, systemic contact reactions, and a miscellaneous group. Excluded from this discussion are the spongiotic reactions resembling pityriasis rosea produced by gold,⁹⁵⁹ captopril,¹³⁴ and other drugs; the phototoxic and photoallergic reactions produced by a variety of drugs;^{960,961} and allergic contact dermatitis resulting from the topical application of various substances. Although there is mild spongiosis in the exanthematous (morbilliform) eruptions, these are histopathologically distinct from the other spongiotic reactions.

Reactions resembling seborrheic or nummular dermatitis have been reported following the use of latanoprost eye drops for lowering intraocular pressure,⁵⁵⁷ and the ingestion of various drugs including cimetidine, methyldopa,⁵⁵⁹ IL-2,⁹⁶² and antituberculous therapy.⁵⁵⁹ The combination of IFN- α -2b plus ribavirin, used in the treatment of hepatitis C infection, has also produced a generalized nummular dermatitis.^{558,963} This is assumed to be a provocation reaction in an individual with a predisposition to the development of

Figure 5.25 Autoeczematization. This case shows spongiosis and characteristic subepidermal edema. (H&E)

Table 5.5 Drugs causing spongiosis*

Allergic contact dermatitis: amide anesthetics, antihistamines (topical), bacitracin, benzocaine, corticosteroids, cosmetics, doxepin, ethylenediamine, fluorouracil, formaldehyde, idoxuridine, lanconazole, melaleuca (tea-tree) oil, mupirocin, neomycin, nickel, NSAIDs, parabens, phenylenediamine, propacetamol, propylene glycol, psoralens, vitamin E preparations

Nummular dermatitis: antimycobacterial drugs (in combination), gold, IFN- α -2b and ribavirin, latanoprost eye drops, mercury (in dental fillings), methylodopa

Seborrheic dermatitis: arsenic, chlorpromazine, cimetidine, gold, IL-2, methylodopa

Pityriasis rosea-like: see Table 5.2

Systemic contact dermatitis: aminophylline, amoxicillin, ampicillin, balsam, cetuximab, chloral hydrate, cimetidine, cinnamon oil, clonidine, codeine, disulfiram, diuretics, erythromycin, gentamicin, hydroxyurea, hypoglycemic agents, immunoglobulins, isoniazid, minoxidil, neomycin, procaine, quinine, roxithromycin, sweetening agents (artificial), synergists, thiamine, zinc in dental fillings

Nonspecific spongiosis: The most common causes (leading to biopsy) are ACE inhibitors, allopurinol, atenolol, calcium channel blockers, NSAIDs (some) and thiazide diuretics (particularly compound ones such as Moduretic®). Specific drugs include amlodipine, calcitonin, epoprostenol, estrogen, etanercept, fluoxetine (Prozac®), gold, indomethacin, immunoglobulin infusion, infliximab, IFN- α with ribavirin, interleukins, lamotrigine, methadone, nifedipine, paroxetine (Aropax®), phenytoin sodium, piroxicam, progesterone, smallpox vaccination, sulfasalazine, tamoxifen, and subcutaneous injection of danaparoid, GM-CSF, heparin, and vitamin K. Intravenous immunoglobulin and chemotherapeutic agents may also produce a spongiotic reaction.

Photoallergic dermatitis: alprazolam, amlodipine, ampiroxicam, chlorthalidone, chlorpromazine, clofibrate, cyclamates, diphenhydramine, droxicam, fenofibrate, flutamide, griseofulvin, ibuprofen, ketoprofen, lomefloxacin, pikeprofen, piroxicam, pyridoxine, quinidine, quinine, ranitidine, sertraline, sulfonamides, tegafur, tetracyclines, thiazides, tolbutamide, triflusal

Phototoxic dermatitis (spongiosis variable; apoptosis ballooning and/or necrosis may be present): amiodarone, carbamazepine, doxycycline, dyes (some clothing), feroxacin, NSAIDs, ofloxacin, phenothiazines, retinoids, sulfonamides, tetrazepam, thiazides, thioxanthenes

*Excluded from consideration are the drugs causing neutrophilic and eosinophilic spongiosis as precursors of vesiculobullous diseases, and the chemicals (largely industry-related) producing irritant contact dermatitis.

an endogenous dermatitis.⁵⁵⁹ An atopic dermatitis-like eruption has been precipitated by infliximab.⁹⁶⁴ A reaction that mimics a spongiotic drug reaction has been reported in the complete DiGeorge syndrome.⁹⁶⁵

Systemic contact dermatitis results from the administration of an allergen to an individual who has been sensitized to that agent by previous contact with it or with a related substance.⁹⁵⁸ Systemic contact dermatitis may present as an exacerbation of vesicular hand dermatitis, as an eczematous flare at sites of previously positive patch tests, or as a systemic eczematous eruption with a predisposition for the buttocks, genital areas, elbow flexures, axillae, eyelids, and side of the neck.⁹⁶⁶ The term 'baboon syndrome' was coined for this eruption.⁹⁶⁶ This is an important category of spongiotic drug reaction in which numerous drugs have been incriminated. In some areas of the world, inhalation of mercury vapor from a broken thermometer accounts for the majority of cases presenting as the 'baboon syndrome'.⁹⁶⁷ Other causes include antibiotics used topically as well as systemically, such as neomycin, erythromycin,⁹⁶⁸ ampicillin, amoxicillin,⁹⁶⁹ roxithromycin, synergists,⁹⁷¹ and gentamicin, as well as procaine, quinine, chloral hydrate, cetuximab,⁹⁷² cimetidine,⁹⁷³ clonidine, minoxidil, codeine, disulfiram, thiamine, isoniazid, cinnamon oil, balsam,⁹⁷⁴ hydroxyurea,⁹⁷⁵ mercury vapor,⁹⁷⁶ papaya juice,⁹⁷⁷ ingested mango flesh,⁹⁷⁸ aminophyl-

line (cross-reacting with ethylenediamine, a stabilizer in creams),⁹⁷⁹ and certain oral hypoglycemic agents, diuretics, and sweetening agents that cross-react with sulfonamides.^{966,980,981} Ingestion of derivatives of the lacquer tree (*Rhus*), used in traditional (folk) medicine,⁹⁸² and the intravenous infusion of immunoglobulins⁹⁸³⁻⁹⁸⁵ are two additional causes of systemic contact dermatitis. Zinc and other alloys in dental fillings are another cause.^{986,987} Metal sensitivity in patients with orthopedic implants is probably a related condition.^{988,989} It is becoming an increasing clinical problem. Patch testing before implantation may help guide the choice of device to be implanted.⁹⁹⁰

The *miscellaneous category* of drugs producing the spongiotic tissue reaction undoubtedly includes agents that should be more appropriately included in other categories. For example, thiazide diuretics are usually included among the agents that produce photosensitive eruptions, but it appears that, on occasions, an eruption is produced that is not confined to sun-exposed areas.^{991,992} Other drugs in this miscellaneous category include calcium channel blockers (e.g., nifedipine),⁹⁹³ ACE inhibitors,⁹⁹⁴ calcitonin, sulfasalazine,⁹⁹² indomethacin,⁹⁹² etanercept,⁹⁹⁵ infliximab,^{964,996,997} epoprostenol,⁹⁹⁸ fluoxetine (Prozac®),⁹⁹⁹ paroxetine (Aropax®), allopurinol,⁹⁹² piroxicam,¹⁰⁰⁰ tamoxifen, alcohol excess,¹⁰⁰¹ methadone,¹⁰⁰² and phenytoin sodium (sensitivity reaction).¹⁰⁰³ The subcutaneous injection of heparin, semisynthetic heparinoids (e.g., danaparoid), or vitamin K₁ may produce an eczematous plaque.¹⁰⁰⁴⁻¹⁰⁰⁷ Whenever treatment with the causative agent is continued, a generalized maculopapular rash may develop in addition to the localized plaque.^{1008,1009} Cross-reactivity to related agents is not uncommon.¹⁰⁰⁸ The infusion of IL-2 or human immune globulin¹⁰¹⁰ and the subcutaneous injection of either IL-6 or granulocyte-monocyte colony-stimulating factor (GM-CSF) have been associated with a spongiotic tissue reaction.¹⁰¹¹⁻¹⁰¹⁴ The palmoplantar erythrodysesthesia produced by various chemotherapeutic medications, most commonly doxorubicin, docetaxel, fluorouracil, and cytarabine, is usually mildly spongiotic. A similar reaction is produced by the epidermal growth factor receptor inhibitors such as sunitinib.¹⁰¹⁵ IFN- α and ribavirin, used in the treatment of hepatitis C, may produce 'eczema-like' lesions;^{585,1016} so too may smallpox vaccination.¹⁰¹⁷ Gold, in addition to causing a pityriasis rosea-like reaction, also produces an eczematous eruption that may last for up to 12 months after the cessation of gold therapy.^{1018,1019} Estrogen and progesterone (usually endogenous) have been associated with a spongiotic reaction (see later).¹⁰²⁰⁻¹⁰²³

The incidence of spongiotic drug reactions is difficult to assess. Some reports make no mention of this type of reaction. One study reported that approximately 10% of cutaneous drug reactions were of 'eczematous' type.¹⁰²⁴ In addition to generalized papules and eczematous plaques, a *fixed eczematous eruption* can also occur, the agents responsible usually being antibiotics.

Histopathology

By definition, there is epidermal spongiosis: this may occur at all levels of the epidermis. Spongiotic vesiculation is sometimes present. A characteristic feature is the presence of exocytosis of lymphocytes and occasionally of eosinophils. Often, there is more exocytosis than would be expected for the amount of spongiosis in the region (Fig. 5.26). Rare Civatte bodies (apoptotic cells) are almost invariably present, but a careful search is usually necessary to find these cells (Fig. 5.27). Small spongiotic vesicles containing lymphocytes are a characteristic feature of pityriasis rosea-like eruptions. In exanthematous eruptions, the spongiosis and exocytosis are confined to the basal layers of the epidermis in a rather characteristic pattern.¹⁰²⁵ Other epidermal changes in spongiotic drug reactions include variable parakeratosis and, in chronic lesions, some acanthosis.

The papillary dermis shows mild to moderate edema, and there is a predominantly perivascular infiltrate of lymphocytes. Eosinophils are

Figure 5.26 (A) Spongiotic drug reaction. (B) There is more exocytosis of inflammatory cells in spongiotic drug reactions than in most other spongiotic diseases. (H&E)

Figure 5.27 Spongiotic drug reaction. The spongiosis is minimal in this area of the biopsy. Note the exocytosis of lymphocytes and an apoptotic keratinocyte. (H&E)

usually present, but this is not invariable. Some of the lymphoid cells appear to be larger than the usual mature lymphocyte. In a study of gold-induced reactions, the lymphocytes were characterized as T-helper cells (CD4⁺).¹⁰¹⁹ Another feature of the infiltrate is its tendency to extend into the mid dermis, somewhat deeper than is usual with other spongiotic disorders. Red cell extravasation is sometimes present in the upper dermis.¹⁰¹⁹ Pigment incontinence is uncommon. Photospongiotic drug reactions are surprisingly common in Australia (Fig. 5.28). Thiazides and calcium channel blockers are often responsible for this pattern (see p. 622).

AUTOIMMUNE PROGESTERONE DERMATITIS

Autoimmune progesterone dermatitis is a rare disorder characterized by recurrent cyclic eruptions during the luteal phase of the menstrual cycle.^{1026,1027} It presents as a pruritic, erythematous eruption with urticarial lesions, eczematous plaques, and erythema multiforme-like lesions. Pustular lesions have been described. Petechiae, palpable purpura, and dermatitis herpetiformis-like lesions are rare manifestations.¹⁰²⁸ The lesions resolve or partly improve after the menses. Lesions localized to the genital area have been described.¹⁰²⁷ Onset of the disease may be from the menarche to the fifth decade. Hormone therapy and infertility treatment may precipitate the disease. Some cases are worsened during pregnancy.

This condition is thought to be an autoallergic/delayed hypersensitivity reaction to endogenous progesterone. Provocation test with intramuscular or oral progesterone can be used. Positive skin tests result from the intradermal injection of progesterone. Serum progesterone antibodies are sometimes detected.¹⁰²⁸ Progesterone-sensitive IFN- γ -producing cells can be detected by the ELISpot assay.¹⁰²⁷

Treatment with estrogen preparations can be used. Desensitization to progesterone has also been carried out successfully.¹⁰²⁹

Histopathology

Autoimmune progesterone dermatitis may show a range of histological appearances from a nonspecific picture to one that mimics specific dermatoses such as erythema multiforme or urticaria.¹⁰³⁰ Epidermal spongiosis is commonly present with acanthosis and rare apoptotic keratinocytes as seen in other spongiotic drug reactions. There is a superficial perivascular infiltrate of lymphocytes, eosinophils, and sometimes neutrophils. The infiltrate is moderately heavy. Pigment-containing melanophages are often present in the papillary dermis.

Figure 5.28 Photospongiotic drug reaction. (A) There is epidermal spongiosis and subepidermal edema. (B) There are many eosinophils in the perivascular infiltrate. (H&E)

ESTROGEN DERMATITIS

Eruptions similar to autoimmune progesterone dermatitis have been reported in women secondary to a hypersensitivity reaction to exogenous or endogenous estrogen. Estrogen dermatitis was first reported by Shelley and colleagues in 1995.¹⁰²⁰ Patients present with a cyclical exacerbation, before each menstrual period, of papulovesicular lesions, urticaria, eczematous lesions, or generalized pruritus.¹⁰³¹ The diagnosis cannot be made without a clinical history. All patients have a positive skin test reaction to estrogens.

Treatment has been successful with a progestin-only pill.¹⁰³² Anti-estrogen therapy with tamoxifen can also be used.

Histopathology

The eczematous lesions are characterized by epidermal spongiosis with variable vesiculation depending on the severity of the process.¹⁰³¹ There is subepidermal edema and a mild to moderately severe superficial

Figure 5.29 Estrogen dermatitis. There is massive urticarial edema. There is no significant spongiosis. (H&E)

perivascular infiltrate of lymphocytes and a few eosinophils. Urticarial lesions will usually be devoid of any spongiosis (Fig. 5.29).

CHRONIC SUPERFICIAL DERMATITIS

Chronic superficial dermatitis (persistent superficial dermatitis, small plaque parapsoriasis,¹⁰³³ digitate dermatosis¹⁰³⁴) is characterized by well-defined, round to oval patches with a fine 'cigarette-paper' scale, usually situated on the trunk and proximal parts of the extremities.^{1033,1035} Individual lesions measure 2–5 cm in diameter, although larger patches, sometimes with a digitate pattern, may be found on the lower limbs, particularly the thighs.¹⁰³⁶ The lesions usually have a reddish-brown color, although the hue is yellowish in a small number of cases.¹⁰³⁷ The term 'xanthoerythrodermia perstans' was applied in the past to these latter cases.^{1034,1038}

Onset of the disease is usually in middle life, and there is a male predominance. The lesions are mostly asymptomatic and persistent, although a minority clear spontaneously.¹⁰³⁹ Chronic superficial dermatitis, unlike large plaque parapsoriasis, with which it has been confused in the past, does not appear to progress to lymphoma,⁹⁴⁸ despite the findings of a dominant T-cell clone in some cases.¹⁰⁴⁰ For various reasons, Ackerman and colleagues regard it as an early stage of mycosis fungoides.^{1041,1042} Others have called it an 'abortive' lymphoma^{1043,1044} or a distinct disorder 'only weakly associated with mycosis fungoides'.¹⁰⁴⁵ Until the clinical significance of clonality and the chain of events leading to tumor progression are better understood, the true nature of this process will remain speculative. The risk of progression to mycosis fungoides is small.

Histopathology^{1033,1036}

Although chronic superficial dermatitis is classified with the spongiotic tissue reaction, it must be emphasized that in this condition the spongiosis is usually only focal and mild. There is usually focal parakeratosis or focal scale crust formation, implying preceding spongiosis. The epidermis is usually acanthotic and, in older lesions, there may be psoriasiform hyperplasia.

A mild infiltrate of lymphocytes and occasional histiocytes is present around blood vessels in the superficial plexus. Cells often extend high in the papillary dermis, a characteristic feature. Exocytosis of these cells is common but mild (Fig. 5.30). There are no interface changes as

Figure 5.30 Chronic superficial dermatitis. (A) This lesion shows confluent parakeratosis that has lifted off from the epidermis, mild acanthosis, and a superficial perivascular lymphocytic infiltrate. (B) The epidermis is only mildly spongiotic and there is focal exocytosis of mature lymphocytes into the epidermis. (H&E)

in pityriasis lichenoides chronica and no atypical lymphoid cells as may occur in mycosis fungoides.

BLASCHKO DERMATITIS

In 1990, Grosshans and Marot described an adult male with acquired, unilateral, relapsing inflammatory lesions, in a linear arrangement along Blaschko’s lines.¹⁰⁴⁶ The designations ‘acquired relapsing self-healing Blaschko dermatitis’ and ‘blaschkitis’¹⁰⁴⁷ have since been applied.¹⁰⁴⁸ The etiology is unknown, but genomic mosaicism has been suggested as the explanation for the distribution. The histopathology is characterized by an acute or subacute spongiotic dermatitis with spongiotic vesiculation.¹⁰⁴⁸ It appears that lichen striatus and blaschkitis are related linear dermatoses forming a spectrum of lesions.¹⁰⁴⁹

PSORIASIS

Spongiosis can occur in the early stages of psoriasis associated with lymphocyte exocytosis. It can be seen in established lesions of psoriasis

Table 5.6 Variants of psoriasis with spongiosis
Early psoriasis/guttate psoriasis
Psoriasis of palms and soles
Erythrodermic psoriasis
Flexural psoriasis
Established psoriasis (rare, may have subtle histopathological features of glucagonoma syndrome as well)
Spongiotic psoriasis

on the palms and soles, leading to difficulties in distinguishing these cases from allergic contact dermatitis. The presence of mounds of scale crust, regularly distributed within the cornified layer (akin to the mounds of parakeratosis containing neutrophils at their summits seen in psoriasis elsewhere on the body), is characteristic of psoriasis on volar surfaces.¹³ There are multiple parakeratotic foci, arranged vertically and alternating with orthohyperkeratosis. Spongiosis is often present in erythrodermic psoriasis and in psoriasis of the flexures. Rarely, an established case of psoriasis will show mild spongiosis, sometimes associated with features seen in the glucagonoma syndrome (see p. 569), such as mild epidermal vacuolation and intracorneal neutrophils. Finally, there are rare cases of psoriasis in which mild spongiosis is a feature in initial and subsequent biopsies, so-called ‘spongiotic psoriasis’. The variants of psoriasis with spongiosis are listed in Table 5.6.

LIGHT REACTIONS

Epidermal spongiosis may be seen in photoallergic dermatitis (see p. 622), phototoxic dermatitis (see p. 620), the so-called ‘eczematous’ form of polymorphic light eruption, and certain persistent light reactions such as actinic reticuloid (see p. 628).

Histopathology

Photoallergic and phototoxic reactions are akin to allergic contact and irritant contact reactions, respectively. They may be morphologically indistinguishable, although in some photoallergic reactions the inflammatory cell infiltrate extends deeper in the dermis. There is usually a superficial and deep perivascular infiltrate of lymphocytes in the papulovesicular form (so-called ‘eczematous’ type) of polymorphic light eruption. The epidermis shows variable spongiosis leading to spongiotic vesiculation. Actinic reticuloid may have a mildly spongiotic epidermis. However, the diagnosis is usually made on the basis of the dense, polymorphous infiltrate in the upper dermis that includes some large lymphoid cells with hyperchromatic nuclei and stellate fibroblasts.

DERMATOPHYTOSES

Dermatophyte infections can present with a spongiotic dermatitis, and clinically they can mimic a range of ‘eczematous’ dermatitides.

Histopathology

In addition to the spongiosis, the stratum corneum is usually abnormal, with compact orthokeratosis or parakeratosis sandwiched between orthokeratotic layers or the presence of neutrophils in the stratum corneum. Sometimes spongiotic pustules are present. The presence of neutrophils within the epidermis or stratum corneum warrants a careful search for hyphae, including the use of the PAS stain.

Figure 5.31 Bullous reaction to a caterpillar bite. There is a characteristic 'bite-like' dermal inflammatory infiltrate. (H&E)

ARTHROPOD BITES

Epidermal spongiosis is a common finding in certain arthropod bite reactions, particularly scabies. Vesicles and, rarely, bullous lesions may develop in response to some arthropods. The spongiosis is usually of eosinophilic type (see p. 107), but certain beetles can produce neutrophilic spongiosis. Contact with moths of the genus *Hylesia* is said to cause vesicular lesions. Although not arthropod related, mention should be made here of cercarial dermatitis (see p. 762), which can mimic a bite reaction.

Histopathology

There is variable spongiosis, sometimes leading to spongiotic vesiculation. Bullae are uncommon (Fig. 5.31). Exocytosis of eosinophils through the epidermis may be present, but eosinophilic spongiosis is quite uncommon. The dermis contains a superficial and deep perivascular infiltrate of lymphocytes and eosinophils; characteristically, there are interstitial eosinophils.

GROVER'S DISEASE

There is a rare variant of Grover's disease, clinically indistinguishable from the other histopathological variants, in which spongiosis is present (see p. 308).

Histopathology

Suprabasal clefting with some overlying dyskeratotic cells and grains will be found in addition to the spongiosis.

TOXIC SHOCK SYNDROME

Small foci of spongiosis containing a few neutrophils and scattered degenerate keratinocytes are a feature of this rare staphylococcal toxin syndrome (see p. 640).

PUPPP

PUPPP (pruritic urticarial papules and plaques of pregnancy), also known as toxic erythema of pregnancy (see p. 256), presents as an intensely pruritic eruption of papules and urticarial plaques toward the end of pregnancy.

Histopathology

The tissue reaction is a subtle lymphocytic vasculitis with variable edema of the papillary dermis. Epidermal spongiosis is present in one-third of cases. There may be focal parakeratosis as well.

PIGMENTED PURPURIC DERMATOSES

Epidermal spongiosis, usually mild, may be present in several clinical variants of the pigmented purpuric dermatoses (see p. 263). The presence of a superficial, band-like infiltrate of inflammatory cells, often associated with a lymphocytic vasculitis, and the deposition of hemosiderin in the upper dermis usually overshadow the spongiosis. Lesions of purpuric contact dermatitis (see p. 119) may closely resemble those of the pigmented purpuric dermatoses.

PITYRIASIS ALBA

Pityriasis alba consists of variably hypopigmented, slightly scaly patches, usually on the head and neck of atopic individuals (see p. 331).

Histopathology

Pityriasis alba should be considered if there is mild epidermal spongiosis with minimal exocytosis and focal parakeratosis in the clinical setting of hypopigmented lesions. There is a reduction in melanin in the basal layer of the epidermis.

ECZEMATOID GVHD

Chronic cutaneous graft-versus-host disease (GVHD) usually presents with lichenoid or sclerodermatous morphology. A novel form of GVHD, characterized by severe and persistent eczematous lesions, has been reported.¹⁰⁵⁰ This is an aggressive chronic dermatitis that requires substantial immunosuppressive therapy to achieve control.^{1050,1051} It has a poor prognosis. None of the patients, nor the marrow donors, had a history of atopy.¹⁰⁵⁰ Grade 2 allograft rejections are characterized by spongiosis and spongiotic vesiculation (see p. 60).

Histopathology

The lesions had combined features of GVHD and spongiosis, which was generally mild and associated with acanthosis. The associated exocytosis of lymphocytes into the epidermis resulted in a superficial resemblance to the Sulzberger–Garbe syndrome, although in this latter condition, apoptotic keratinocytes are surrounded by one, not several, lymphocytes as seen in GVHD.

ERUPTION OF LYMPHOCYTE RECOVERY

Mild epidermal spongiosis is usually present (see p. 63).

LICHEN STRIATUS

Lichen striatus is a linear, papular eruption with a predilection for children and adolescents (see p. 50). There is a lichenoid tissue reaction involving a number of adjacent dermal papillae. The overlying epidermis is acanthotic with mild spongiosis and exocytosis of inflammatory cells. Sometimes the spongiosis has pityriasiform features. In summary, it is a lichenoid/spongiotic dermatosis.

ERYTHRODERMA

Erythroderma (exfoliative dermatitis) may complicate various spongiotic dermatitides, including atopic dermatitis, seborrheic dermatitis, photosensitive eczematous processes (e.g., actinic reticuloid), nummular dermatitis, stasis dermatitis, and contact dermatitis (see p. 591).

Histopathology

The underlying, pre-existing dermatosis is not always diagnosable when erythroderma supervenes. Often, the amount of spongiosis is mild, even in cases with a pre-existing spongiotic dermatitis; there may even be psoriasiform hyperplasia of the epidermis without spongiosis in these circumstances. Spongiosis is usually present in the congenital erythroderma accompanying Omenn's syndrome.¹⁰⁵²

MYCOSIS FUNGOIDES

Mycosis fungoides is a cutaneous T-cell lymphoma that evolves through several clinical stages (see p. 1173). An unequivocal diagnosis is sometimes difficult to make in the early stages of the disease.

Histopathology

There has been controversy in the past regarding the presence or absence of spongiosis in lesions of mycosis fungoides.^{1053,1054} In one

study, slight spongiosis was found in 38% of lesions in the patch/plaque stage and moderate spongiosis in a further 17%.¹⁰⁵⁴ There was no microvesiculation.¹⁰⁵⁴ The epidermis appears to contain increased amounts of acid mucopolysaccharides. Other features that allow mycosis fungoides to be distinguished from other spongiotic disorders include the presence of a band-like infiltrate of lymphocytes (some atypical) and often eosinophils and plasma cells in the upper dermis associated with papillary dermal fibrosis. There is usually prominent epidermotropism of the lymphoid cells.

Spongiosis may also be found in the Sézary syndrome (see p. 1182) and in papuloerythroderma of Ofuji (see p. 592).

ACROKERATOSIS PARANEOPLASTICA

Acrokeratosis paraneoplastica (Bazex's syndrome) is characterized by mild spongiosis (see p. 590). Other changes include hyperkeratosis, focal parakeratosis, exocytosis of lymphocytes, and scattered apoptotic keratinocytes.

INTRODUCTION

The vesiculobullous reaction pattern is characterized by the presence of vesicles or bullae at any level within the epidermis or at the dermoepidermal junction. Pustules, which are vesicles or bullae containing numerous neutrophils or eosinophils, are included in this reaction pattern. Vesiculobullous lesions result from a defect, congenital or acquired, in the adhesion of keratinocytes. Accordingly, it is important to have an understanding of the mechanisms involved in normal epidermal cohesion.

Epidermal cohesion

The integrity of the epidermis, which serves to protect humans from the external environment, is maintained by intercellular junctional complexes composed of tight junctions, adherens junctions, and desmosomes.¹ They are composed of adhesion molecules that have an important role in cell–cell and cell–matrix adhesion.^{2,3} Signal transmission (intercellular communication) is a major function of gap junctions, composed of various polypeptides, the most important of which are connexins.⁴ Their role in cell–cell adhesion appears to be a minor one. A review of gap junctions was published in 2002.⁵ Adhesion molecules are transmembrane proteins, the extracellular domains of which are homophilic and the intracellular portions linked to the cytoskeleton of the cell.

There are four major families of adhesion molecules – cadherins, integrins, selectins, and the immunoglobulin superfamily – which are localized to two specialized intercellular junctions known as *desmosomes* (including hemidesmosomes) and the *adherens junction*.⁶ The more recently characterized tight junction is considered at the end of this section. In addition to their unique proteins, they also contain members of the immunoglobulin superfamily.¹ Focal adhesions (labile structures seen in cultured keratinocytes and postulated to exist in the skin) are included with the adherens junction group. Desmosomes are well-defined, plaque-like areas of point contact that are easily seen in the spinous layer. The adherens junction is less well defined. Some work suggests that it may be situated near desmosomes.⁷ Desmosomes and adherens junctions further differ from one another in three respects:

1. The subclass of adhesion molecule present
2. The composition of the cytoplasmic plaque (discussed later)
3. The nature of the associated cytoskeletal element.

These aspects are considered further in the sections discussing adhesion molecules and cytoplasmic plaques.

Adhesion molecules

As indicated previously, there are four families of adhesion molecules. They are sometimes divided into two groups – those that mediate cell–cell adhesion, such as the cadherins and immunoglobulin superfamily, and those that mediate cellular adhesion to matrix molecules, such as the selectins. The integrins are capable of mediating both types of adhesion. The cadherins are the most important group in keratinocyte cohesion, although the integrins have a role in basal cells, particularly in the hemidesmosomes. Cadherins and integrins are important for the maintenance of tissue integrity and in signal transduction during skin development.⁸ Only brief mention is made of the other families in the discussion that follows.

Cadherins

The cadherins are calcium-dependent adhesion molecules that extracellularly can attach to other cadherins; that is, they are homophilic.³ There are two major subfamilies of cadherins: the first, known as *classic cadherins* (E-cadherin), are found in the adherens junctions

where their cytoplasmic domains link with cytoplasmic anchoring molecules (including β -catenin, type XIII collagen,⁹ ZO-1, and vinculin) in the cytoplasmic plaques and that, in turn, connect with actin filaments of the cytoskeleton; the second group of cadherins, which are localized to desmosomes (*desmosomal cadherins*), are linked eventually to keratin intermediate filaments via plakoglobin and the desmoplakins of the cytoplasmic plaques.^{10,11} In both adherens junctions and desmosomes, a cadherin tail binds to an armadillo family member (β -catenin/plakoglobin in adherens junctions or plakoglobin in desmosomes), which in turn associates with a cytoskeletal linking protein (α -catenin in adherens junction and desmoplakin in desmosomes).¹² That is, desmosomes contain proteins from at least three distinct gene families: cadherins (desmogleins and desmocollins), armadillo proteins (plakoglobin, plakophilins (PKP1–3), and p0071, now called PKP4), and plakins (desmoplakin I and II, plectin, epiplakin, and the cell envelope proteins envoplakin and periplakin).¹² As just mentioned, there are two major groups of desmosomal cadherins – the *desmogleins* and the *desmocollins*. Both have been mapped to chromosome 18.¹⁰ To date, four desmoglein and three desmocollin genes have been identified.

The *desmogleins*, which have large cytoplasmic domains, exhibit a tissue- and differentiation-specific pattern of expression.¹³ Of the four desmogleins, desmoglein 1 is the major desmosomal cadherin in the skin. It is expressed throughout the epidermis, but it is expressed primarily in the upper layers of the epidermis. It is the target antigen in pemphigus foliaceus. Desmoglein 2 is ubiquitous and is found in most simple epithelia and basal epidermis, whereas desmoglein 3 is found primarily in the spinous layer. It decreases gradually toward the upper layers of the epidermis. It is the target antigen in pemphigus vulgaris.¹³ Desmoglein 4 is a newly identified member of the desmoglein family that is expressed in the suprabasal layers of the epidermis.¹⁴ The genes for these proteins – *DSG1*, *DSG2*, and *DSG3* – are clustered within a small region in 18q12.1. Mutations in the *DSG1* gene cause the dominantly inherited skin disease striate palmoplantar keratoderma type I.

Less is known about the *desmocollins*. They have shorter intracytoplasmic domains than the desmogleins. They may play a key role in initiating desmosome assembly.¹⁰ Desmocollin 1 is the major category. Its distribution mirrors that of the corresponding desmoglein 1.¹⁴ The genes for the desmocollins – *DSC1*, *DSC2*, and *DSC3* – map to 18q12.1, the same region that harbors the desmoglein genes. Both IgA pemphigus and pemphigus foliaceus (particularly the endemic form) may sometimes be associated with autoantibodies to desmocollin.¹⁵ Desmocollin 3 has been found to be an autoantigen in pemphigus vulgaris.¹⁶

Integrins

The integrin family of adhesion molecules is involved in cell–cell and cell–matrix adhesions, particularly in the hemidesmosomes of basal keratinocytes and the ‘focal adhesions’ of cultured keratinocytes. Integrins are heterodimers with an α and a β chain. Fourteen α and eight β chains have been described, but only a limited number of permutations have so far been described in the skin: $\alpha_2\beta_1$, $\alpha_3\beta_1$, and $\alpha_6\beta_4$.¹⁷ The first two subtypes are found in the lateral and basal aspects of basal cells, whereas $\alpha_6\beta_4$ is located in the hemidesmosomes. The genes for the two chains of $\alpha_6\beta_4$ integrin are *ITGA6* and *ITGB4*. Epiligrin (laminin 332) is an adhesive ligand for $\alpha_3\beta_1$ and $\alpha_6\beta$ integrins. Other extracellular matrix ligands include other laminins and fibronectin.¹⁷ The laminins are of great importance in maintaining epidermal adhesion to the dermis.¹⁸ For example, mutations of genes that encode the α_3 , β_3 , and γ_2 chains of laminin 332 cause variants of junctional epidermolysis bullosa, and autoantibodies to laminin 332 chains have been associated with mucous membrane pemphigoid and rare variants of bullous lupus erythematosus as well as severe bullous disease in dogs and other species.¹⁹

Immunoglobulin superfamily

The immunoglobulin superfamily has one or more immunoglobulin-like domains. Included in this group are molecules concerned with adhesion to lymphocytes and the intercellular adhesion molecule (ICAM). They have no significant role in keratinocyte cohesion,³ but they do contribute to the tight junction that has barrier rather than cohesion functions.

Selectins

The selectins are mainly involved in endothelial cell adhesion. They have no significant role in the epidermis.³

Cytoplasmic plaques

Cytoplasmic plaques are dense, submembranous regions of the intercellular junctions, measuring 14–20 nm in thickness. They are composed of filament-binding proteins that connect with the cytoplasmic domain of the cadherins and the filaments of the cytoskeleton. In desmosomes, the plaques connect with keratin intermediate filaments, whereas in the adherens junctions they connect with actin filaments.

The composition of the cytoplasmic plaques is different in the two junctions; only *plakoglobin* is common to both. In the adherens junctions, the cytoplasmic plaques contain α - and β -catenins. In desmosomes, the cytoplasmic plaques consist primarily of *desmoplakins 1 and 2*, antibodies to which are found in paraneoplastic pemphigus. The desmoplakins play a pivotal role in anchoring the network of intermediate filaments to desmosomes.²⁰ Other proteins (e.g., IFAP-300) may enhance this association.²¹ The first mutation to be described in desmoplakin was in a family with autosomal dominant striate palmoplantar keratoderma (OMIM 125647) (see p. 295).²² An autosomal recessive mutation in desmoplakin gives rise to Carvajal syndrome (OMIM 605676), which comprises dilated cardiomyopathy, woolly hair, and keratoderma (see p. 295).²² The desmoplakins, along with the bullous pemphigoid antigen 1, plectin, and the cell envelope proteins envoplakin and periplakin, belong to the so-called ‘intermediate filament-associated proteins’,¹⁰ now known as the plakin family.²² An absence of plectin from the hemidesmosomes has been found in a variant of epidermolysis bullosa simplex with associated muscular dystrophy. Autoantibodies to plectin (450 kDa) have been reported in a patient with a bullous pemphigoid-like eruption.²³ One study suggests that inflammation in inflammatory bowel disease may expose plectin, prompting a secondary immune response that can cross-react with skin, resulting in bullous pemphigoid as a form of ‘epitope spreading’ in patients who have undergone colostomy or ileostomy.²⁴ Other constituents of the desmosomal cytoplasmic plaque include the armadillo proteins plakoglobin and plakophilins 1, 2, 3, and 4.^{12,25} Plakophilins are essential for the formation and function of desmosomes because they are involved in the recruitment and normal association of the other desmosomal proteins.²⁶ Plakophilin 1 is expressed primarily in the suprabasal layers of stratifying epithelia.²⁷ It is absent in patients with ectodermal dysplasia-skin fragility syndrome (OMIM 604536). Mutations in the plakoglobin gene result in the palmoplantar keratoderma known as Naxos disease (see p. 295). Absence of plakophilin 1 has been associated with skin fragility and hypohidrotic ectodermal dysplasia.²⁸

Tight junctions

Tight junctions play an important role in the formation of the epidermal barrier. Their role in cell cohesion is minimal. They are a gatekeeper of the paracellular pathway, forming a circumferential, belt-like structure involving cells of the granular layer, in normal epidermis.¹ Tight junctions contain the proteins occludin; ZO-1; cingulin; claudin-1, -4, -5, and possibly others; and JAM-1, a member of the immunoglobulin superfamily.^{1,29,30} It appears that ZO-1 acts as a link between

JAM-1 and the claudins.¹ Tight junction proteins are destroyed in various inflammatory diseases of the skin, including psoriasis and atopic dermatitis.²⁹

In summary, epidermal cohesion is a complex process involving the adhesion molecule families – cadherins and integrins – concentrated in areas known as desmosomes and adherens junctions. They have extracellular domains (homophilic in the case of cadherins) and intracellular ones that connect with filament-binding proteins (plakoglobin and catenins or desmoplakins) in cytoplasmic plaques. These proteins connect with filaments of the cytoskeleton, such as actin and keratin intermediate filaments.

Classification of vesiculobullous diseases

Early lesions should always be biopsied to ensure that a histopathological diagnosis can be made. Once regeneration of the epidermis commences or secondary changes such as infection or ulceration occur, accurate diagnosis of a vesiculobullous lesion may not always be possible. Furthermore, in some blistering diseases, special techniques such as direct immunofluorescence (IF), split-skin immunofluorescence,^{31–34} or electron microscopy may assist in making the diagnosis. Identification of the target antigen may be of diagnostic importance in some of the autoimmune blistering diseases (Table 6.1). Interestingly, some of the same structural proteins targeted by autoantibodies in patients with acquired autoimmune bullous disorders are mutated in some patients with inherited bullous diseases.³⁵

The following three morphological features may need to be assessed in the diagnosis of vesiculobullous lesions:

1. The anatomical level of the split
2. The mechanism responsible for the split
3. The inflammatory cell component (in the case of subepidermal blisters).

These various aspects are considered in greater detail.

Anatomical level of the split

The blister may form at any one of four different anatomical levels. The split may be subcorneal (intracorneal splitting is included in this category), within the spinous or malpighian layers, suprabasilar, or beneath the epidermis (subepidermal). In the case of subepidermal blisters, several different anatomical levels may be involved, but these are ‘submicroscopic’ and require the use of electron microscopy or other special techniques (discussed later) for their elucidation.

The mechanism responsible for the split

There are several mechanisms by which blistering can result – spongiosis, acantholysis, and ballooning degeneration of keratinocytes. *Spongiosis* refers to the presence of intercellular edema. In some of the disorders showing the spongiotic reaction pattern (see Chapter 5), the edema may be so pronounced that there is breakdown of the intercellular connections, leading to vesicle formation. Clinically visible vesicles occur in a small proportion of cases with the spongiotic reaction pattern. *Acantholysis* refers to the loss of attachments between keratinocytes, resulting in the formation of rounded, detached cells within the blister. Acantholysis may result from damage to the intercellular connections due to the deposition of immune complexes, as in pemphigus, or from abnormalities of the tonofilament–desmosome complexes, which may be an acquired abnormality or have a heredo-familial basis. Acantholysis may also occur secondary to other processes such as ballooning degeneration. *Ballooning degeneration* of keratinocytes refers to the swelling of these cells that follows their infection with certain viruses. The ballooning results in rupture of desmosomal attachments and vesicle formation. Sometimes a few acantholytic cells are present in vesicles as an incidental phenomenon, resulting from the action of enzymes released by neutrophils in the

Table 6.1 Autoimmune bullous diseases – target antigens			
Disease	Target antigen	Site of antigen	Other minor antigens reported and comments
Pemphigus foliaceus	Desmoglein 1	Desmosomes of upper epidermis	Desmocollin – antibodies to this alone in some endemic cases
Herpetiform pemphigus	Desmoglein 1	Desmosomes of upper epidermis	Desmoglein 3, desmocollin 3
IgA pemphigus (SPD type)	Desmocollin 1	Desmosomes (transmembrane)	
IgA pemphigus (IEN type)	Desmoglein 1 or 3	Desmosomes	Desmocollin 1, non-desmosomal transmembranous protein
Pemphigus vulgaris	Desmoglein 3	Desmosomes of lower epidermis	Desmocollin, 85-kDa antigen (in pemphigus vulgaris–Neumann), desmoglein 1
Epidermolysis bullosa acquisita	Type VII collagen	Anchoring fibrils	IgA antibody to plectin; similar antigen in bullous SLE
Paraneoplastic pemphigus	Desmoglein 1, 3 Desmoplakin 1, 2	Cytoplasmic plaques	Envoplakin, BP230, periplakin, γ -catenin, plectin, 170 kDa, desmocollin 2 and 3
Bullous pemphigoid	BPAg1 (230)	Hemidesmosome	80% have antibodies to 230-, 30% to 180-, and 20% only to 180-kDa antigen Others reported – 240, 190, 138, 120, 125, 105 kDa, plectin, desmoglein 3
	BPAg2 (180)	Transmembrane protein (NC16A domain)	
Pemphigoid gestationis	BPAg2 (180)	See above	Others reported – 200 kDa, BP230
Dermatitis herpetiformis	Tissue transglutaminase (?TG3)	Gut, ?site in skin	IgA deposits haphazard in papilla
Linear IgA bullous dermatosis	LABD97, LAD-1	Lamina lucida	97- and 120-kDa antigens are degradation products of BP180 NC-1 domain of type VII collagen and others
	LAD285 (10–25%)	Sublamina densa	
Ocular cicatricial pemphigoid	Plectin	Conjunctiva	IgA antibody, may be heterogeneous
Cicatricial pemphigoid	BPAg2 (180) Epiligrin (laminin 332)	Against extracellular (C-terminal) domain α_3 subunit of laminin 5	Many other epitopes exist on antigen Epiligrin cases uncommon (10% or more)
Deep lamina lucida pemphigoid	105 kDa	Lower lamina lucida	Clinically resembles TEN, pemphigus vulgaris
Anti-p200 pemphigoid	200 kDa	Lower lamina lucida	Clinically resembles BP, DH, or LABD

accompanying inflammatory infiltrate. The presence of a few acantholytic cells in these circumstances should not be misinterpreted as indicating that acantholysis is the pathogenetic mechanism responsible for the blister in such a case. *Junctional separation* is sometimes included as a mechanism of blister formation, but it is a heterogeneous process involving different mechanisms and different anatomical levels within the basement membrane zone.

Inflammatory cell component

In the case of subepidermal blisters, it is usual to subclassify them further on the basis of the predominant cell in the inflammatory infiltrate in the underlying dermis. In some subepidermal blisters, the proportion of eosinophils and neutrophils may vary from case to case and with the age of the lesion. These caveats must always be kept in mind when a subepidermal blister with neutrophils or eosinophils is biopsied. The presence of neutrophils within intraepidermal blisters may also have relevance to the diagnosis, even though this aspect is not used in the subclassification of intraepidermal blisters. A detailed study of the inflammatory cell infiltrate in various blistering diseases has been published.³⁶ Many cells expressing CD68 were present in all of the diseases studied. CD68 is not specific for histiocytes/macrophages.³⁶

Other morphological features

Although the key features in the assessment of any vesiculobullous lesion are the anatomical level of the split, the mechanism responsible for the split, and the nature of the inflammatory cell infiltrate, as

discussed previously, the presence of changes in keratinocytes may assist in making a diagnosis in several diseases. Examples include the presence of dyskeratotic cells in Darier’s disease, the presence of multinucleate giant cells in certain virus-induced blisters, and confluent epidermal necrosis in toxic epidermal necrolysis and in severe erythema multiforme. Shrunken keratinocytes (Civatte bodies) may be seen in bullous lichen planus, bullous fixed drug eruptions, erythema multiforme, and paraneoplastic pemphigus.

INTRACORNEAL AND SUBCORNEAL BLISTERS

In this group of vesiculobullous diseases, the split occurs within the stratum corneum or directly beneath it. In addition to the conditions discussed here, subcorneal blisters or pustules have been reported uncommonly as a manifestation of epidermolysis bullosa simplex, acute generalized pustulosis and other pustular vasculitides, and pyoderma gangrenosum (see p. 267).³⁷ There is one report of a patient with vegetative plaques resembling pemphigus vegetans and a subcorneal spongiform pustule with marked acanthosis of the epidermis on histological examination.³⁸ Subcorneal splitting is usually present in the **peeling skin syndrome** (see p. 318). It may be congenital (see p. 318) or acquired. Azathioprine has been implicated in acquired cases.³⁹ Subcorneal pustules have been reported in adult Still’s disease.⁴⁰

Other causes of intracorneal or subcorneal blisters are discussed below.

IMPETIGO

Impetigo is an acute superficial pyoderma that occurs predominantly in childhood (see p. 638). *Staphylococcus aureus* is the usual organism isolated from this condition. There are two clinical forms of impetigo – a common vesiculopustular type and a rare bullous type.

Histopathology

In impetigo, there are subcorneal collections of neutrophils. A few acantholytic cells are sometimes present, particularly in bullous impetigo, as a result of the action of enzymes released from neutrophils. Acantholysis is never as prominent in impetigo as it is in pemphigus foliaceus. Gram-positive cocci can usually be demonstrated in impetigo, another distinguishing feature of this condition.

Subcorneal pustules, sometimes resembling impetigo, can be seen in some cases of listeriosis.

STAPHYLOCOCCAL ‘SCALDED SKIN’ SYNDROME

The staphylococcal ‘scalded skin’ syndrome (SSSS) is discussed in detail with the bacterial infections on page 639. It results from the production of an epidermolytic toxin by certain strains of *S. aureus*.⁴¹ This toxin cleaves the extracellular domain of desmoglein 1.⁴²

Histopathology

It is usually difficult to obtain an intact blister in SSSS because the stratum corneum may be cast off during the biopsy procedure or the subsequent processing of the specimen. A few acantholytic cells and neutrophils are usually present in intact blisters or on the surface of the epidermis if its roof has been shed (Fig. 6.1). Organisms are not usually present in the affected skin, in contrast to bullous impetigo. There is usually only a sparse inflammatory cell infiltrate in the upper dermis, in contrast to bullous impetigo and pemphigus foliaceus in which the infiltrate is usually heavier.

DERMATOPHYTOSIS

Subcorneal and intraepidermal blisters are sometimes seen in the dermatophytoses, particularly on the hands and feet. The presence of neutrophils in the stratum corneum or within the epidermis should

Figure 6.1 Staphylococcal ‘scalded skin’ syndrome. A thin layer of altered stratum corneum forms the roof of the blister. Inflammation is minimal. (H&E)

always prompt consideration of an infectious etiology, including fungi. Candidosis is another uncommon cause of subcorneal blistering.

PEMPHIGUS FOLIACEUS

Pemphigus foliaceus, which accounts for approximately 10% of all cases of pemphigus, is one of the less severe forms of the disease.^{43,44} There are recurrent crops of flaccid bullae that readily rupture, resulting in shallow erosions and crusted erythematous plaques.^{45,46} A stinging or burning sensation is sometimes present. Lesions may be localized to the face and trunk initially, but the condition usually spreads to involve large areas of the body. Rarely, the lesions remain localized to a site, such as the nose.⁴⁷ Mucous membrane involvement is rare.^{48,49} Umbilical involvement in pemphigus vulgaris and pemphigus foliaceus has been emphasized in one study; the reason for this is yet to be elucidated.⁵⁰ No age, including childhood^{51–58} and the neonatal period,⁵⁹ is exempt, although the majority of cases present in late middle life. Postpartum onset⁶⁰ and neonatal involvement, following passive transfer of antibodies across the placenta, have been reported.^{61–63}

Rare clinical presentations have included generalized erythroderma,⁶⁴ lesions resembling eruptive seborrheic keratoses,^{65–67} and in other instances erythematous and vesicular lesions suggestive of dermatitis herpetiformis.^{68–73} This latter group, also known as *pemphigus herpetiformis* and *herpetiform pemphigus*, has autoantibodies directed against desmoglein 1 (dsg1), indicating its close relationship to pemphigus foliaceus (discussed later).^{74,75} Rarely, the clinical and histological features of pemphigus foliaceus may change to those of pemphigus vulgaris; the antibody profile also changes.⁷⁶ Such cases are probably examples of intermolecular epitope spreading.⁷⁷ This is also the explanation for the conversion of pemphigus foliaceus into bullous pemphigoid^{78,79} and for mixed features of these two diseases.⁸⁰ Although epitope spreading is a mechanism of protection from pathogens, it propagates autoimmunity.⁸¹ Patients with features of both pemphigus vulgaris and pemphigus foliaceus clinically, histologically, and immunologically have been reported.^{82,83}

Pemphigus foliaceus has been reported in association with bullous pemphigoid,^{84,85} lupus erythematosus,⁸⁶ dermatomyositis,⁸⁷ rheumatoid arthritis, IgA nephropathy,⁸⁸ myasthenia gravis,^{48,89,90} thymoma,^{91,92} lymphoma,⁹³ prostate cancer,⁹⁴ herpes simplex infection (eczema herpeticum),^{95,96} silicosis,⁹⁷ lichen planus,⁹⁸ Graves’ disease,⁹⁶ mycosis fungoides,⁹⁹ and multiple autoimmune syndrome type 2.¹⁰⁰ Both pemphigus foliaceus and psoriasis can be associated with exfoliative erythroderma. Accordingly, there are reports of patients initially diagnosed as having erythrodermic psoriasis who proved to have pemphigus foliaceus¹⁰¹ and also instances of pemphigus foliaceus arising in patients with psoriasis, one example occurring after treatment of the latter with multiple cycles of narrowband UVB therapy.¹⁰² The disorder has been complicated by disseminated herpes simplex infection and lesions of cytomegalovirus.¹⁰³ Pemphigus foliaceus may be induced by sunlight^{104,105} and by ionizing radiation.¹⁰⁶ It developed in a patient with cutaneous squamous cell carcinoma (SCC) that metastasized to regional lymph nodes. The production of anti-dsg1 antibodies started when the SCC metastasized.¹⁰⁷ It has also been associated with the use of penicillamine,¹⁰⁸ bucillamine,¹⁰⁹ gold, pyritinol, rifampin (rifampicin),¹¹⁰ captopril,^{111,112} enalapril,¹¹³ ramipril,¹¹⁴ fosinopril,¹¹⁵ cephalosporins, levodopa, aspirin,¹¹⁶ methimazole (thiamazole), and α -mercaptopyrionylglycine (tiopronin).^{117–119} Some drugs that contain thiol groups can produce acantholysis, *in vitro*, in human skin explants.¹²⁰ Pemphigus foliaceus has been exacerbated by a tetanus vaccination.¹²¹ Localized disease has been produced by the application of topical imiquimod.^{122,123}

Pemphigus foliaceus is the most common form of pemphigus complicating the use of penicillamine.^{108,124,125} Pemphigus develops in nearly 10% of those taking penicillamine for prolonged periods, and it may

persist for many months after the drug is discontinued.¹²⁶ Sometimes the eruption that ensues is not typical of a specific type of pemphigus but shares clinical or immunohistological features of different types of the disease.^{127–129}

Pathogenesis

Pemphigus foliaceus results from the formation of autoantibodies, mainly of the IgG4 subclass, that react with several different antigenic epitopes on the amino-terminal region of *dsg1*, a 160-kDa transmembrane glycoprotein, which is present in desmosomes.^{13,130–134} The amino-terminus of *dsg1* appears to be a key region for the intercellular adhesion of cadherins. In certain cases, the antibodies appear to react with desmocollins, the other subtype of desmosomal cadherins, or other antigens.^{135–138} The expression of *dsg1* is highest in specimens from the upper torso, excluding the scalp.^{139,140} It is expressed primarily in the upper layers of the epidermis.¹³ *Dsg1* is expressed at a much lower level than *dsg3* in oral mucosa.¹⁴¹ This suggests that *dsg3* may be sufficient for cell–cell adhesion in oral mucosa, with consequently no oral involvement in patients with pemphigus foliaceus.¹⁴¹ Neonates are protected from the effect of the passive transfer of maternal autoantibodies across the placenta by possessing *dsg3* in the upper levels of the epidermis.^{142,143} The antibodies found in patients with drug-induced pemphigus,^{144,145} and in some patients with pemphigus vulgaris, also react with *dsg1*.¹⁴⁶ The antibodies themselves are pathogenic,¹³⁴ but complement, including the terminal complement sequence (membrane attack complex),¹⁴⁷ is also an important mediator in the detachment of the epidermal cells. The use of plasminogen activator knockout mice suggests that there is no requirement for proteases in blister formation.^{104,148} Antibody levels fluctuate during the course of the disease and have some correlation with disease activity. However, a recent study has shown that the predominant binding of anti-*dsg1* antibodies to the amino-terminus of *dsg1* persists despite the activity stage of the disease, including periods of remission.¹⁴⁹ The availability of recombinant *dsg1* has facilitated the development of antigen-specific plasmapheresis as a therapeutic strategy.¹³⁴ A subset of pemphigus foliaceus patients exhibits pathogenic autoantibodies against both *dsg1* and *dsg3*. The figure is less than 7%.¹⁵⁰

Cytokines also have a pathogenic role in this disease.¹⁵¹ Tumor necrosis factor- α (TNF- α) levels are found in the serum and blister fluid. Increased cytokine production is the likely mechanism of the localized pemphigus foliaceus produced by topical imiquimod.¹²² Epidermal keratinocytes can be induced to produce proinflammatory cytokines and other mediators such as bradykinin. The kinin system might have a potential role in the pathogenesis of acantholysis in pemphigus foliaceus, along with TNF- α .¹⁵²

Endemic pemphigus foliaceus¹⁵³

The variant endemic pemphigus foliaceus is also known by the Portuguese expression *fogo selvagem* ('wild fire') and as Brazilian pemphigus foliaceus.^{154–157} It affects mostly children and young adults and is endemic in certain rural areas of South America, particularly areas of Brazil.^{158,159} In contrast, the new form of endemic pemphigus reported from Colombia, also called El Bagre-EPF (El Bagre, 'the catfish', is a municipality in Colombia), predominantly affects 40- to 60-year-old men, as well as a few postmenopausal women, and the patients are primarily miners who also engage in farming.^{160,161} Furthermore, the Colombian variant more closely resembles pemphigus erythematosus.¹⁶⁰ High levels of mercury have been found in the skin of these patients.¹⁶² Ocular involvement has been reported in patients with extensive skin involvement, and antibodies to meibomian glands and tarsal muscle have been detected in this variant.¹⁶³ Similarly, hair loss was known to be a feature of severe endemic pemphigus foliaceus in the pre-corticosteroid area, and autoantibodies within the hair follicle

have been found in these patients.¹⁶⁴ Cases resembling the Brazilian form of the disease have been reported from Venezuela.¹⁶⁵ An 'endemic' form of pemphigus has been reported in Tunisia,¹⁶⁶ although its 'endemic' nature has not been clearly demonstrated.¹⁶⁰ *Dsg1* antibodies are prevalent in Tunisian patients with hydatidosis and leishmaniasis, and this may be a predisposing factor for the later development of pemphigus foliaceus.¹⁶⁷ The epidemiology strongly suggests an environmental factor,¹⁶⁸ possibly a virus, and this is supported by the finding of elevated levels of thymosin α_1 in many affected individuals.^{169,170} Most of these affected individuals live within a 10- to 15-km radius of rivers and streams, where black flies of the *Simulium* type are found. It has been suggested that the fly may trigger a response in genetically predisposed individuals.¹⁷¹ This predisposition does not seem to involve a defect in innate immunity.¹⁷² It has been found that anti-*dsg1* IgG4 antibodies cross-react with a salivary gland protein, LJM11, from the sand fly *Lutzomyia longipalpis*, suggesting a mechanism by which an arthropod bite could initiate endemic pemphigus foliaceus in susceptible individuals.¹⁷³ The endemic variant has an abrupt onset and a variable course.¹⁷⁴ Sunlight can exacerbate the condition.¹⁷⁵ Improvement has been recorded in a patient who developed HIV infection.¹⁷⁶ Familial cases occur in 10%, in contrast to their rarity in the more usual form of pemphigus foliaceus.^{177,178} In many cases, the circulating intercellular antibodies have similar antigenic specificity to those found in the non-endemic form of the disease,^{179–181} although in some, antibodies to the desmocollins, rather than to *dsg1*, have been present. Furthermore, their localization may be at a different site on the cell surface (discussed later).¹⁸² Recent work suggests that the anti-*dsg1* response in the endemic disease involves IgM class antibodies, and this sets it apart from other forms of pemphigus.¹⁸³ The prevalence of antibodies against *dsg1* is high among normal subjects living in endemic areas, and the onset of the disease is preceded by a sustained antibody response.^{171,184} There is serological evidence that the incidence of *dsg1* antibodies may be declining in some endemic areas of Brazil.¹⁸⁵ Circulating antibodies, using indirect IF and human skin as substrate, can be demonstrated in 70% of cases.¹⁸⁶ This figure is much higher (90%) if more sensitive enzyme-linked immunosorbent assay (ELISA) techniques are used.¹⁸⁷ A small number of cases also have antibodies to *dsg3*.¹⁸⁷ Of interest is the finding that the intraperitoneal injection into mice of IgG from patients with endemic pemphigus foliaceus causes acantholysis in the animals.¹⁸⁸ In addition to the humoral-immune response, cell-mediated mechanisms involving CD4⁺ lymphocytes are also involved.¹⁸⁹

In the Colombian form of the disease, all sera have antibodies to *dsg1*; however, there are additional antibodies, as observed in paraneoplastic pemphigus, but there is no association with neoplasia.¹⁶¹ The antibodies are to desmoplakin 1, envoplakin, and periplakin.¹⁶⁰

Treatment of pemphigus foliaceus

Corticosteroids are the treatment of choice, but because this is a chronic disease that frequently requires long-term therapy, other adjuvants have been added for their steroid-sparing effect. Sometimes these other agents are used as monotherapy.¹⁹⁰ They include azathioprine, cyclophosphamide, gold, methotrexate, chlorambucil, cyclosporine (ciclosporin), mycophenolate mofetil, dapsone, hydroxychloroquine,⁵⁷ plasmapheresis, extracorporeal photopheresis, and intravenous immunoglobulin.¹⁹⁰ Isolated cases, refractory to other therapies, have been successfully treated with etanercept¹⁵¹ and rituximab.^{64,191} There is experimental evidence that ectopic superficial expression of desmoglein 2 can limit epidermal blister formation produced by pemphigus foliaceus antibodies and exfoliative toxin-A.¹⁹² The plant lectin jacalin specifically binds to O-linked Thomsen–Friedenreich carbohydrate structures on *dsg1* and inhibits its interaction with pemphigus foliaceus IgG, thereby interfering with the latter's pathogenicity; this may have potential therapeutic value.¹⁹³

Histopathology

Established lesions of pemphigus foliaceus of both endemic and non-endemic forms show a superficial bulla with the split high in the granular layer or directly beneath the stratum corneum.¹⁹⁴ The bulla contains fibrin, some neutrophils, and scattered acantholytic keratinocytes. No bacteria are present, unlike bullous impetigo.¹⁹⁴ A localized clinical variety with a peau d'orange clinical appearance was characterized by acantholysis exclusively involving follicular infundibula.¹⁹⁵ The earliest change appears to be the formation of vacuoles in the intercellular spaces in the upper layers of the epidermis.¹⁹⁶ These expand, leading to cleft formation. Uncommonly, eosinophilic spongiosis is seen as a precursor lesion, and transitions between this picture and that of pemphigus foliaceus may be seen. Eosinophilic spongiosis appears to be more common in pemphigus foliaceus in some African races.⁶⁷ Neutrophilic spongiosis is a rare occurrence in pemphigus foliaceus;^{197,198} its occurrence is usually related to the deposition of IgA or the herpetiform type (herpetiform pemphigus).⁷² Neutrophilic pustules are another uncommon manifestation of pemphigus foliaceus.¹⁹⁹

In late lesions of pemphigus foliaceus, the epidermis may be hyperplastic, with overlying focal parakeratosis and some orthokeratosis.²⁰⁰ Dyskeratotic cells with hyperchromatic nuclei and somewhat resembling the 'grains' found in Darier's disease are a distinctive feature of the granular layer (Fig. 6.2). In the rare mixed forms of the disease, both suprabasal acantholysis and subcorneal clefting with acantholysis are present.⁸³

The superficial dermis is edematous with a mixed inflammatory cell infiltrate that usually includes both eosinophils and neutrophils. In drug-induced lesions, eosinophils may predominate in the dermal infiltrate.

With direct IF, there is intercellular staining for IgG and C3 in both affected and normal skin.^{201,202} Sometimes the staining is localized to the upper levels of the epidermis (Fig. 6.3).^{203,204} Rarely, these immunoreactants may be present along the basement membrane, even in cases that clinically resemble pemphigus foliaceus rather than pemphigus erythematosus (discussed later).²⁰⁵ In a few instances, IgA rather than IgG has been present in the intercellular regions.^{206,207} The term 'IgA pemphigus' has been used for these cases. Indirect IF demonstrates circulating antibodies in nearly 90% of cases of non-endemic pemphigus foliaceus.²⁰⁸ A subset of cases of pemphigus foliaceus also has positive indirect IF using a rat bladder epithelial substrate – a feature more typical of paraneoplastic pemphigus.²⁰⁹

Figure 6.2 Pemphigus foliaceus. Dyskeratotic cells with hyperchromatic nuclei are a distinctive feature in the granular layer in this older lesion.

Reflectance confocal microscopy can be used to suggest an initial diagnosis of pemphigus, including pemphigus foliaceus, although it is not considered a replacement for histopathologic and immunofluorescence studies. The diagnosis is suggested when two of three criteria are met: acantholytic clefts in a lesion, acantholytic clefts in normal-appearing adjacent skin, and multiple dilated blood vessels in lesional skin.²¹⁰

Electron microscopy

Acantholysis in pemphigus foliaceus appears to result from separation of the nonspecific junctions and subsequent rupture of desmosomal junctions.²⁰⁰ The tonofilament–desmosomal complexes remain intact, although irregular bundles of tonofilaments are found within the acantholytic cells.²¹¹ Internalization of intact desmosomes also occurs.²¹² Clinically unaffected mucosa in endemic pemphigus foliaceus shows widening of the intercellular spaces with distended, elongated cytoplasmic projections.²¹³ Nikolsky-positive skin is characterized by widening between desmosomes, decreased numbers of desmosomes, and hypoplastic desmosomes in lower epidermal layers, with acantholysis sometimes demonstrable only in upper epidermal layers; lesional skin shows both upper epidermal acantholysis and separation of hypoplastic desmosomes from adjacent cells.²¹⁴ Immunoelectron microscopy shows immunoglobulins deposited over the plasma membrane of the keratinocytes and permeating the desmosomal junctions in the endemic form,^{182,211} whereas in the usual form there is affinity for desmosomes and separated attachment plaques in the upper layers of the epidermis.^{215–217}

PEMPHIGUS ERYTHEMATOSUS

Pemphigus erythematosus (Senear–Usher syndrome), which accounts for approximately 10% of all cases of pemphigus,^{44,218} is a variant of pemphigus foliaceus that combines some of the immunological features of both pemphigus and lupus erythematosus.⁴⁵ It usually develops insidiously with erythematous, scaly, and crusted plaques in a butterfly distribution over the nose and malar areas.²¹⁹ It may also involve other 'seborrheic areas' such as the scalp, pectoral, and interscapular regions, as well as intertriginous areas. Usually, there is no visceral involvement. Pemphigus erythematosus may persist almost indefinitely as a localized disease.⁷⁰ Sunlight sometimes adversely affects its course.⁴³ This condition is extremely rare in children.^{220,221}

Pemphigus erythematosus is occasionally found in association with other autoimmune diseases, especially myasthenia gravis with an

Figure 6.3 Pemphigus foliaceus. The intercellular IgG is deposited throughout much of the epidermis but spares the basal layer. (Direct immunofluorescence)

accompanying thymoma.²²² Rare cases of concurrent pemphigus erythematosus and systemic lupus erythematosus (SLE) have been documented.²²³ There are reports of its association with parathyroid adenoma,²²⁴ internal cancers,²²⁵ burns,²²⁶ and X-radiation. Drugs that may induce pemphigus erythematosus²¹⁹ include ceftazidime,²²⁷ penicillamine,^{228–230} propranolol,²¹⁹ captopril,²³¹ pyritinol,²¹⁹ thiopronine,²³² and heroin.²³³

Antinuclear antibodies and circulating antibodies to dsG1 are often present. Antibodies to DNA are usually absent,²³⁰ but in one case both anti-DNA and multiple anti-ENA antibodies were present.²³⁴ In one case with mucocutaneous pemphigus vulgaris with higher titers of dsG1 than dsG3, the patient developed cutaneous lesions resembling pemphigus erythematosus.²³⁵ The treatment is similar to that used for pemphigus foliaceus,²¹⁰ although some cases can be refractory to standard treatment and require extensive immunosuppressive therapy.²³⁴

Histopathology

The appearances are identical to those of pemphigus foliaceus, with a subcorneal blister containing occasional acantholytic cells (discussed previously).²³⁶ Eroded and crusted lesions may develop.

Direct IF usually demonstrates IgG and/or complement, both in the intercellular spaces and at the dermoepidermal junction.^{237,238} The intercellular staining may be more pronounced in the upper layers of the epidermis. The lupus band test is sometimes positive in uninvolved skin.²³⁰ A possible explanation for the basement membrane zone deposits has been provided in a study of three cases of pemphigus foliaceus that were subjected to UVA phototherapy. Oktarina *et al.* found evidence for release of desmoglein 1 fragments, which appear to form immune complexes with circulating anti-desmoglein 1 IgG antibodies and deposit along the basement membrane zone. A similar mechanism may occur in pemphigus erythematosus and would also explain the localization of these lesions to sun-exposed skin.²³⁹

HERPETIFORM PEMPHIGUS

Herpetiform pemphigus (pemphigus herpetiformis) is a rare entity that combines the clinical features of dermatitis herpetiformis and the immunopathology of pemphigus, usually the foliaceus type (discussed previously).^{68–75} Such cases account for approximately 7% of all cases of pemphigus.²⁴⁰ Clinically, there are erythematous, urticarial plaques and vesicles in herpetiform arrangement. Severe pruritus is often present.²⁴⁰ Mucous membranes are uncommonly involved. It has been reported in association with SLE,²⁴¹ psoriasis,²⁴² solid tumors,^{243,244} and endemic pemphigus foliaceus.²⁴⁵ Its association with psoriasis is sometimes related to treatment with ultraviolet light.²⁴⁶ Cases may evolve into pemphigus foliaceus.

Most cases have circulating autoantibodies to desmoglein 1, the pemphigus foliaceus antigen.²⁴⁷ A few cases with antibodies to the pemphigus vulgaris antigen, desmoglein 3, have been reported.^{248,249} A case with IgA and IgG antibodies to desmoglein 1 and IgG antibodies to desmocollin 3 has been reported.²⁵⁰ Recent studies suggest that the antigenicity in herpetiform pemphigus may be even more complex. One case of herpetiform pemphigus lacked anti-desmoglein 1 or 3 antibodies; immunoelectron microscopy indicated positivity at the keratinocyte cell surface but not on the desmosomes.²⁵¹ In another case, there were antibodies both to desmoglein 1 and to full-length 180-kDa bullous pemphigoid antigen; there was no staining for IgG along the epidermal basement membrane zone with direct IF, but circulating anti-basement membrane zone antibodies were detected at a titer of 1:10.²⁵² Still another study found concurrence of bullous pemphigoid and herpetiform pemphigus, with IgG antibodies to desmogleins 1 and 3, desmocollins 1–3, and the NC16a domain of bullous pemphigoid 180-kDa antigen; direct IF featured basement membrane zone staining for C3 as well as intercellular IgG deposition.²⁵³

Histopathology

The characteristic features of herpetiform pemphigus are eosinophilic spongiosis with the formation of intraepidermal vesicles.²⁴⁷ Variable numbers of neutrophils may be present, leading to the formation of neutrophilic spongiosis or subcorneal pustules with both eosinophils and neutrophils. Acantholysis is minimal or absent.

Direct IF shows the deposition of IgG, with or without C3, on the cell surfaces of keratinocytes, as seen in pemphigus. There is usually superficial accentuation,²⁴² but in cases with antibodies to desmoglein 3, the deposition may be more prominent on the lower layers of the epidermis.²⁴⁹

SUBCORNEAL PUSTULAR DERMATOSIS

Subcorneal pustular dermatosis is a rare, chronic, relapsing, vesiculopustular dermatosis with a predilection for the trunk, particularly intertriginous areas, and the flexor aspect of the limbs.^{254–258} Atypical presentations, including lesions confined to the extensor aspects of the extremities, have been reported.²⁵⁹ It usually spares the face and mucous membranes, and there are usually no constitutional symptoms.^{260,261} The condition is more common in women, particularly occurring in the fourth and fifth decades of life. Cases purporting to be subcorneal pustular dermatosis in children²⁶² have been disputed,²⁶³ but some cases appear to be genuine examples of the disease.²⁶⁴

The pustules are flaccid. They are initially sterile, but secondary infection sometimes develops. A transient erythematous flare surrounds the pustules in the early stages.²⁵⁵

The etiology and pathogenesis remain unknown. A small number of patients have had an associated monoclonal gammopathy, most commonly of IgA type.^{260,265–270} Some of these cases have been associated with intercellular deposits of IgA and would now be reclassified as IgA pemphigus (discussed later). Whether subcorneal pustular dermatosis survives as an entity must await further reports. Pyoderma gangrenosum has been described in patients with subcorneal pustular dermatosis, usually in association with an IgA monoclonal gammopathy.^{271,272} In two cases, the lesions of subcorneal pustular dermatosis developed several hours after the performance of echography.²⁷³ Other rare associations include aplastic anemia,²⁷⁴ AIDS,²⁷⁵ Sjögren's syndrome,²⁷⁶ seronegative arthritis,²⁷⁷ multiple sclerosis,²⁷⁸ and SLE. Subcorneal pustular dermatosis is regarded by some authorities as a variant of pustular psoriasis.^{279,280} This confusion has arisen, in part, because cases not conforming to the original 1956 description of Sneddon and Wilkinson have been reported misleadingly as cases of subcorneal pustular dermatosis. Some of these cases have been examples of the annular variant of pustular psoriasis.^{256,281} Note that 7 of the 23 purported cases of subcorneal pustular dermatosis seen at the Mayo Clinic subsequently developed generalized pustular psoriasis.²⁸² A child has been reported with a diffuse sterile pustular eruption that progressed from annular pustular psoriasis to subcorneal pustular dermatosis.²⁸³

Pustular eruptions with some histological or clinical resemblance to subcorneal pustular dermatosis have been reported following the ingestion of isoniazid,²⁸⁴ diltiazem,²⁸⁵ gefitinib,²⁸⁶ paclitaxel,²⁸⁷ the cephalosporins,²⁸⁸ and amoxicillin.²⁸⁹ New lesions have been precipitated in a patient with subcorneal pustular dermatosis following the ingestion of dapsone and of quinidine sulfate.²⁹⁰ Sterile, subcorneal pustules sometimes form in pustular vasculitis.

TNF- α is increased in subcorneal pustular dermatosis; it may be responsible, in part, for the activation of neutrophils that is a feature of this condition.²⁹¹

The treatment of choice is dapsone.²⁵⁸ Therapeutic alternatives include retinoids,²⁹² PUVA, broadband or narrowband UVB, colchicine, and corticosteroids.²⁵⁸ Cyclosporine can be used with prednisolone.²⁹³ Infliximab, an antibody to TNF- α , has been used successfully

to treat recalcitrant disease;²⁹⁴ adalimumab has also been used to treat this disease.²⁹⁵

Histopathology

The subcorneal pustule is filled with neutrophils, with an occasional eosinophil. Neutrophils also migrate through the epidermis, but they do not form spongiform pustules.²⁵⁶ The pustule appears to 'sit' on the epidermis (Fig. 6.4), and usually it causes no depression of the latter. An occasional acantholytic cell may be present in older lesions, a result of the activity of the proteolytic enzymes released from neutrophils.²⁵⁶ Mitotic figures are usually absent within the epidermis, unlike pustular psoriasis.²⁹⁶

A mixed superficial perivascular inflammatory cell infiltrate is present in the underlying dermis. In early lesions, the infiltrate includes quite a few neutrophils.

Direct IF is usually negative, although immunoreactants have been described in the epidermis in rare cases.²⁶⁵ Several cases have been reported of a condition resembling subcorneal pustular dermatosis clinically but in which a biopsy of the lesions showed intercellular IgA. Such cases are now classified as IgA pemphigus, although a case could be made for the retention of some of them as variants of subcorneal pustular dermatosis.²⁹⁷ This subject is discussed further in the following section.

IgA PEMPHIGUS

IgA pemphigus is an autoimmune, intraepidermal vesiculobullous eruption, with variable acantholysis and the presence of intercellular deposits of IgA within the epidermis.^{207,208,240,298-302} There are recurring crops of pruritic papules and vesicles that evolve into eroded and crusted plaques, involving the trunk and proximal extremities.^{303,304} Other sites may be involved, but mucous membranes are usually spared. A pemphigus vegetans-like variant of IgA pemphigus can be associated with inflammatory bowel disease.^{305,306} The subcorneal pustular dermatosis type (discussed later) may have lesions limited to intertriginous areas.³⁰⁷ The other variant (IEN type) may have lesions with central crusts and peripheral vesiculation (so-called sunflower lesions).³⁰⁷ An atypical case with antibodies to dsg3 has been reported that had involvement of the oral mucosa and colon.³⁰⁸ Its antibodies were of both IgG and IgA class.³⁰⁸ IgG/IgA pemphigus has also presented as a malar erythema.³⁰⁹ These mixed IgA/IgG cases are probably a different entity (see later). There has been one case of IgA pemphigus associated with a submucosal duodenal tumor that proved to be diffuse large B-cell lymphoma; treatment of the lymphoma with rituximab-CHOP therapy resulted in the disappearance of the skin lesions.³¹⁰

Circulating IgA antibodies are present in approximately half of the cases, whereas an IgA monoclonal gammopathy is present in nearly 20% of cases.^{300,311} Other terms used for this entity in the past include intraepidermal IgA pustulosis,³¹¹ intraepidermal neutrophilic IgA dermatosis (IEN type),^{299,312,313} IgA herpetiform pemphigus, intercellular IgA vesiculopustular dermatosis,³¹⁴ subcorneal pustular dermatosis with IgA deposition,³¹⁵ and intercellular IgA dermatosis.³¹⁶

IgA pemphigus is a clinically heterogeneous condition reflecting differences in the autoantigens involved.³¹⁷ Two distinct groups are recognized: the first with a subcorneal pustule, resembling subcorneal pustular dermatosis (SPD type), and IgA deposition confined to the upper epidermis;^{315,318} and a second group, which sometimes presents with clinical herpetiform lesions^{319,320} and intraepidermal pustules, associated with a more widespread distribution of IgA throughout the epidermis (IEN type).²⁹⁹ The presence of cases with overlap features supports the notion that this is one disease with variable expression.^{300,319} In a review of the 49 cases published up to the year 2000, 25 were of the SPD type, 19 were of the IEN type, and the other 5

Figure 6.4 (A) Subcorneal pustular dermatosis. (B) The subcorneal pustule contains fibrin and a modest number of neutrophils. (C) Sometimes neutrophils are sparse in the blister. Presumably they have been lost following biopsy. (H&E)

cases were unclassified.³²¹ In 6 of the SPD type, a monoclonal IgA gammopathy was present. Some of these cases have been previously diagnosed as subcorneal pustular dermatosis (discussed previously). In studies of the subcorneal group, the antibodies have recognized bovine desmocollins and/or human desmocollin 1 (Dsc1) or neither.^{302,314,321–323} Using a cDNA transfection method and cultured COS-7 cells, all recent cases of the subcorneal type have had IgA autoantibodies reacting with Dsc1.³²⁴ In the intraepidermal group, some studies have reported that the antibodies react to desmoglein 1, desmoglein 3, or one of the desmocollins,^{300,314,317,325} but other studies have concluded that the antigen is unknown.³²⁴ A recent case of IEN type had IgA and IgG antibodies directed against Dsc1.³⁰⁷

Cases have been reported in children^{316,326,327} and also in adult males with HIV infection.^{313,328}

Dapsone is the drug of first choice. It may be used alone or combined with topical steroids and colchicine.³⁰³ Retinoids have been used when dapsone has failed or cannot be tolerated.³⁰³ Methotrexate, oral corticosteroids, and adalimumab and mycophenolate mofetil³⁰⁴ have also been used. Cases refractory to standard therapy continue to be reported.³²⁹

Histopathology

In the SPD type, there are subcorneal pustules with variable but usually mild acantholysis, whereas in the IEN type there are intraepidermal pustules. There is usually a mixed inflammatory cell infiltrate in the underlying dermis. A case of IgA pemphigus (foliaceus) has been reported that resembled the more usual cases of pemphigus foliaceus without any neutrophilic infiltration.²⁰⁷ Neutrophilic spongiosis, suggestive of IgA pemphigus, has been reported in a case of pemphigus foliaceus devoid of IgA. A rare variant of the IEN type, which occurred in a child on immunosuppressive drugs, had features of pemphigus vegetans with epidermal hyperplasia and intraepidermal pustules.³³⁰

Direct IF shows intercellular deposition of IgA in the epidermis. There is usually increased intensity of staining in the upper layers of the epidermis in the SPD type.³⁰⁴ In the IEN type, the IgA staining is usually throughout the entire epidermis. IgG is also present in a small number of cases, which have usually been called **IgA/IgG pemphigus**. This appears to be a distinct entity in which the antibodies often target one of the desmogleins, but this is not absolute.^{307,331–333} A recent case of IgG/IgA pemphigus had IgG and IgA anti-desmoglein 3 antibodies and IgA anti-desmoglein 1 antibodies; microscopically, the lesions showed prominent acantholysis but lacked intraepidermal neutrophilic microabscesses.³³⁴

Electron microscopy

On immunoelectron microscopy, the deposits have been found along the keratinocyte cell membrane and not confined to the region of the desmosomes.³³⁵ In a study of both types of IgA pemphigus, it was found that the IgA in the sera of the subcorneal pustular dermatosis type reacts with the extracellular domain of desmocollins, whereas in the intraepidermal neutrophilic variant, a non-desmosomal transmembranous protein may be the target antigen.¹⁵

Differential diagnosis of intracorneal and subcorneal forms of pemphigus

Due to the level of splitting – subcorneal, often through the granular cell layer – *pemphigus foliaceus* can be confused with *bullous impetigo* and *subcorneal pustular dermatosis*. Acantholysis is usually, but not always, more evident in pemphigus foliaceus, and occasionally, suprabasilar acantholysis can also be observed. Pemphigus foliaceus tends to be less pustular than those two diseases, with occasional exceptions, such as some cases of herpetiform pemphigus. Direct IF can permit a definitive diagnosis because among these diseases, positive intercellular IgG and C3 staining is seen only in pemphigus foliaceus. The same

superficial epidermal acantholysis is also characteristic of pemphigus erythematosus, and this finding permits separation from lupus erythematosus, which it can resemble both clinically and, partially, on direct IF because basement membrane zone staining resembling a ‘lupus band’ may also be observed. Paraneoplastic pemphigus shows changes resembling *erythema multiforme*, but most often there are at least foci of suprabasilar acantholysis, and intercellular staining on direct IF is confirmatory of the diagnosis. The morphologic findings of the *subcorneal pustular dermatosis*-like variant of IgA pemphigus can be virtually identical to those of the disease it resembles. In fact, as discussed previously, subcorneal pustular dermatosis may be undergoing redefinition as an entity. However, there are clearly examples of subcorneal pustular eruptions that lack positive intercellular IgA deposition on direct IF study. It appears that in order to recognize this variant of pemphigus, IF studies are essential.

INFANTILE ACROPUSTULOSIS

Infantile acropustulosis is an uncommon pustular dermatosis characterized by recurrent crops of intensely pruritic vesiculopustules on the distal parts of the extremities of infants.^{336–344} The lesions measure 1–2 mm in diameter. Its onset is at birth or in the first few months of life, and resolution occurs at 2 or 3 years of age. There is a predilection for black males. Infantile acropustulosis is common among internationally adopted children (countries such as Vietnam, Ethiopia, and Russia) from crowded living conditions with a high prevalence of scabies infestation.³⁴⁵ The etiology is unknown, although some cases are said to have followed scabies.^{341,346–348} Peripheral eosinophilia and atopy³³⁹ have been present in several patients. It has been successfully treated with topical maxacalcitol, an analog of active vitamin D.³⁴⁹

Infantile acropustulosis, erythema neonatorum toxicum, and transient neonatal pustular melanosis can be grouped together as the ‘pustular dermatoses of infancy’ (see later) because of their overlapping clinical and histological features. Three other neonatal pustular eruptions are mentioned for completeness. **Transient cephalic neonatal pustulosis** is thought to be related to infection with *Malassezia* sp. (see p. 695).³⁵⁰

Congenital erosive and vesicular dermatosis, which heals with a characteristic reticulated supple scarring, is of unknown etiology.³⁵¹ Fewer than 20 cases of this entity have been reported.^{352,353} It is characterized by the presence of erosions and vesicles at birth, usually affecting approximately 75% of the body. The lesions heal with reticulated scarring in weeks to months. A case mimicking junctional epidermolysis bullosa had persistent lesions at 9 years of age.³⁵⁴ The scarring and erosions of the scalp resemble the Rapp–Hodgkin syndrome, in which there is a mutation in the *TP63* gene, but such a mutation was not identified in one case report.³⁵⁵

An unusual vesiculopustular eruption has been reported in infants with **Down syndrome and myeloproliferative disorders**.^{356,357} The skin lesions appear mainly on the face either from birth or soon afterwards, especially at sites where pressure has been applied.³⁵⁸ There are immature myeloid cells in subcorneal spongiotic vesicles. The cells are strongly myeloperoxidase positive on immunohistochemistry. The lesions disappear over weeks to years as the white blood cell count normalizes.^{359,360} A transient myeloproliferative disorder has also been reported in neonates with a normal karyotype and a trisomy 21 in blast cells.³⁶¹

The condition originally reported in infants as ‘eosinophilic pustular folliculitis’ has a predilection for the scalp.³⁶² It has been renamed ‘eosinophilic pustulosis of the scalp’ on the basis of an interfollicular rather than a follicular infiltrate. It has been claimed that “this disorder has more clinicopathological similarities with acropustulosis of infancy than with Ofuji’s disease” (see p. 463).^{362,363} Neonatal eosinophilic pustulosis that presents with grouped pustules on the cheek is a similar condition.³⁶⁴

Histopathology³⁴⁰

In early lesions, there is an intraepidermal pustule containing neutrophils and sometimes varying numbers of eosinophils.³⁴¹ This progresses to form a subcorneal pustule. There is a sparse perivascular mixed inflammatory cell infiltrate in the upper dermis.

In *congenital erosive and vesicular dermatosis with reticulated supple scarring*, the histology has been variable with no consistent pattern. There may be well-defined vesicles in the papillary dermis. The epidermis may be intact, eroded, or ulcerated. Other cases have shown a mixed dermal infiltrate without vesicles³⁶⁵ or edema with a predominantly neutrophilic infiltrate.³⁶⁶ Scarring with a polymorphous dermal infiltrate is seen in older lesions.³⁶⁶ In another case, there were many “Civatte’s bodies in the dermis suggesting previous keratinocytes’ necrosis.”³⁵² There was subepidermal cleavage.

ERYTHEMA TOXICUM NEONATORUM

Erythema toxicum neonatorum is a common, self-limited entity that appears within the first few days of life as erythematous macules, papules, and pustules, mostly located on the trunk.^{367–371} Delayed onset has been reported.³⁷² There is no racial predilection. The lesions resolve within a few days, leaving no sequelae. The etiology remains elusive.^{373,374} Various inflammatory mediators have been demonstrated in the skin by immunohistochemistry.^{375,376}

Histopathology^{367,377}

There are subcorneal or intraepidermal pustules, filled with eosinophils and related to the orifices of the pilosebaceous follicles.³⁶⁷ An inflammatory infiltrate composed predominantly of eosinophils is present in the upper dermis in the vicinity of the follicles, and there is some exocytosis of these cells into the epithelium of the involved follicles.³⁶⁷

The histological appearances resemble those of eosinophilic pustular folliculitis, but the clinical features of the two conditions differ.³⁷⁸

TRANSIENT NEONATAL PUSTULAR MELANOSIS

Transient neonatal pustular melanosis is an uncommon condition that presents at birth with pigmented macules, often with a distinct collarette of scale, and vesiculopustules that are clustered beneath the chin, on the forehead, the neck, and the back, and sometimes on the extremities.^{379–381} The vesiculopustules usually resolve after several days, often transforming into pigmented macules. The pigmented lesions persist for several weeks or more and then slowly fade.³⁷⁹ The etiology of the condition is unknown, but there appears to be a predilection for black races.³⁷⁹ Furthermore, there is an increased incidence of squamous metaplasia in the placentas of affected neonates.³⁴⁴

Histopathology³⁷⁹

The vesiculopustules are intracorneal or subcorneal collections of neutrophils, admixed with fibrin and a few eosinophils. There may be a mild infiltrate of inflammatory cells around vessels in the upper dermis.

The pigmented macules show increased melanin in the basal and suprabasal keratinocytes but, surprisingly, there is no melanin in the dermis.

ACUTE GENERALIZED EXANTHEMATOUS PUSTULOSIS

Acute generalized exanthematous pustulosis (AGEP), also known as toxic pustuloderma, is an uncommon, rapidly evolving pustular eruption

characterized by the development of sterile, miliary pustules on an erythematous background. The lesions may have a targetoid appearance.⁶⁷ Lesions localized to the face and neck were present in one case.³⁸² Fever and a peripheral blood leukocytosis are usually present. The eruption occurs within hours or days of the ingestion of certain drugs and resolves rapidly after cessation of the offending agent.³⁸³ In a small number of cases, a bacterial or viral infection, including enterovirus or cytomegalovirus, has been implicated.^{384–386} A spider bite³⁸⁷ and echinococcosis have also been associated with this condition.^{388,389} In rare cases, no etiology can be demonstrated.³⁹⁰ The lesions are nonfollicular, in contrast to the follicular pustules that may occur in the anticonvulsant hypersensitivity syndrome.³⁹¹ Some patients have a history of underlying psoriasis, ulcerative colitis, or thyroiditis. The lesions of AGEP can usually be distinguished from pustular psoriasis.^{392,393} Cases with overlap features between AGEP and toxic epidermal necrolysis have been reported.³⁹⁴

Numerous drugs have been implicated in the etiology, particularly antibiotics of the β -lactam, cephalosporin, and macrolide type (Table 6.2).^{395–398} Specific drugs implicated include carbamazepine, furosemide (frusemide), acetaminophen (paracetamol),³⁹⁹ allopurinol,^{67,400,401} itraconazole,^{402,403} quinidine,³⁹⁵ diltiazem,^{397,404–407} pholcodine,⁴⁰⁸ pseudoephedrine,^{409,410} bamifylline,⁴¹¹ trimethoprim-sulfamethoxazole,^{412,413} cefuroxime,³⁹⁸ cephalixin,⁴¹³ cefepime,⁴¹⁴ pristinamycin,³⁹⁷ piperacillin/tazobactam,³⁹⁶ chloramphenicol,⁴¹⁵ gentamicin,⁴¹⁶ teicoplanin,^{417,418} levofloxacin,⁴¹⁹ roxithromycin,⁴²⁰ vancomycin,⁴²¹ doxycycline, nystatin,⁴²¹ erythromycin, penicillin, clindamycin,⁴²² ciprofloxacin, amoxicillin,^{423,424} amoxicillin-clavulanic acid,⁴²⁵ terbinafine,^{397,426–431} ceftriaxone,⁴³² icodextrin,⁴³³ mercury, morphine,⁴³⁴ thalidomide,⁴³⁵ thallium,⁴³⁶ intracavernous prostaglandin E₁,⁴³⁷ ticlopidine,⁴³⁸ dalteparin,⁴³⁹ pentoxifylline,⁴⁴⁰ phenytoin, propafenone,⁴⁴¹ metronidazole,⁴⁴² simvastatin,⁴⁴³ nifedipine, ibuprofen,⁴⁴⁴ nimesulide,³⁸² olanzapine,⁴⁴⁵ clemastine,⁴⁴⁶ paracetamol with bromhexine,⁴⁴⁷ chromium picolinate,⁴⁴⁸ chemotherapy drugs,⁴⁴⁹ sennoside,⁴⁵⁰ azathioprine,⁴⁵¹ cytarabine,⁴⁵² amphotericin B,⁴⁵³ enalapril,⁴⁵⁴ imipenem,⁴¹³ lansoprazole,⁴¹⁹ famotidine, cimetidine,⁴⁵⁵ hydroxyzine,⁴⁵⁶ icodextrin,⁴⁵⁷ hydrochlorothiazide,⁴⁵⁸ antimalarials such as chloroquine, proguanil, and hydroxychloroquine,^{459–461} high-dose prednisolone,⁴⁶² isotretinoin,⁴⁶³ meropenem,⁴⁶⁴ radiocontrast media,⁴⁶⁵ lapatinib,⁴⁶⁶ oral ketoconazole,⁴⁶⁷ clopidogrel,⁴⁶⁸ azathioprine (in a patient with ulcerative colitis),⁴⁶⁹ topical diphenhydramine,⁴⁷⁰ methylphenidate,⁴⁷¹ docetaxel,⁴⁷² daptomycin,⁴⁷³ etodolac,⁴⁷⁴ celecoxib,⁴⁷⁵ telavancin (a bactericidal agent used in MRSA infections),⁴⁷⁶ allylisopropylacetylurea,⁴⁷⁷ tocilizumab,⁴⁷⁸ erlotinib,⁴⁷⁹ intravenous immunoglobulin,⁴⁸⁰ galantamine,⁴⁸¹ acyclovir,⁴⁸² methimazole,⁴⁸³ gemcitabine,⁴⁸⁴ etanercept,⁴⁸⁵ quetiapine,⁴⁸⁶ levetiracetam,⁴⁸⁷ paroxetine,⁴⁸⁸ and traditional remedies including the ingestion of lacquer chicken^{455,489} and the herbal medication velvet antler.⁴⁹⁰ Other herbal remedies and so-called recreational drugs have also been implicated.^{491,492} Cutaneous patch testing, using the suspected drug, may be used to confirm the diagnosis.⁴⁹³ In one case, AGEP was precipitated by the patch test carried out to determine the drug eliciting an initial AGEP eruption.⁴⁹⁴

It has been suggested that patients who develop this eruption have an underlying tendency to develop a pattern of immune dysregulation characterized by a T-helper 1 (Th1) cytokine pattern.³⁹³ Th17 cells and their cytokine, interleukin-22 (IL-22), have been found to be elevated in the peripheral blood of patients with AGEP. The latter, in combination with IL-17, may stimulate IL-8 production by keratinocytes, which in turn could explain the accumulation of neutrophils within the epidermis in this disease.⁴⁹⁵

The treatment of AGEP is conservative: stop any drugs that may have triggered the eruption and treat symptomatically with emollients and antipruritics while awaiting spontaneous resolution.⁴⁹⁶ This occurs with superficial desquamation over 1 or 2 weeks.⁴⁹⁶ Topical corticosteroids have also been used.

Table 6.2 Drugs causing acute generalized exanthematous pustulosis				
Acetaminophen	Ciprofloxacin	Gemcitabine	Methylphenidate	Quetiapine
Acyclovir	Clemastine	Gentamicin	Metronidazole	Quinidine
Allopurinol	Clindamycin	Herbal and traditional remedies (lacquer chicken, velvet antler)	Morphine	Radiocontrast media
Allylisopropylacetylurea	Clopidogrel	Hydrochlorothiazide	Nifedipine	Recreational drugs
Amoxicillin (with and without clavulanic acid)	Cytarabine	Hydroxyzine	Nimesulide	Roxithromycin
Amphotericin B	Dalteparin	Ibuprofen	Nystatin	Sennoside
Antimalarials	Daptomycin	Icodextrin	Olanzapine	Simvastatin
Azathioprine	Diltiazem	Imipenem	Paracetamol with bromhexine	Teicoplanin
Bamifylline	Diphenhydramine (topical)	Immunoglobulin, intravenous	Paroxetine	Telavancin
Carbamazepine	Docetaxel	Isotretinoin	Penicillin	Terbinafine
Cefepime	Doxycycline	Itraconazole	Pentoxifylline	Thalidomide
Ceftriaxone	Enalapril	Ketoconazole	Phenytoin	Thallium
Cefuroxime	Erlotinib	Lansoprazole	Pholcodine	Ticlopidine
Celecoxib	Erythromycin	Lapatinib	Piperacillin–tazobactam	Tocilizumab
Cephalexin	Etanercept	Levetiracetam	Prednisolone	Trimethoprim–sulfamethoxazole
Chemotherapy drugs	Etodolac	Levofloxacin	Pristinamycin	Vancomycin
Chloramphenicol	Famotidine	Mercury	Propafenone	
Chromium picolinate	Furosemide	Meropenem	Prostaglandin E1 (intracavernous)	
Cimetidine	Galantamine	Methimazole	Pseudoephedrine	

Figure 6.5 (A) Acute generalized exanthematous pustulosis. (B) There is superficial epidermal pustulation and neutrophilic spongiosis. (H&E)

Histopathology

The usual picture is a subcorneal or superficial intraepidermal pustule with mild spongiform pustulation at the margins (Fig. 6.5). This latter change is never as prominent as the spongiform pustules seen in pustular psoriasis. The pustules frequently contain eosinophils in addition to neutrophils.⁴⁹⁷ There is usually some exocytosis of neutrophils adjacent to the pustules. Scattered apoptotic keratinocytes are often present.⁴²⁰

The papillary dermis is usually edematous, and there is a heavy mixed inflammatory cell infiltrate in the upper dermis. Eosinophils are often present, a distinguishing feature from pustular psoriasis. In a small number of cases, a leukocytoclastic vasculitis is present; this was found in only one case out of a large series of 102 hospitalized patients.⁴⁹⁷ Less commonly, there is subepidermal pustulation that may be in continuity with the intraepidermal pustules.⁴⁵⁵ Similar cases have been reported in the past as acute generalized pustulosis or included with the pustular vasculitides. A case clinically presenting as AGEp,

associated with clindamycin and levofloxacin therapy, showed subcorneal pustules but also an atypical mononucleated dermal infiltrate composed of CD3⁺ and CD30⁺ cells, consistent with a lymphomatoid drug eruption. The eruption resolved within 1 week of discontinuing both drugs.⁴⁹⁸

Differential diagnosis

Acute generalized pustulosis, or *pustulosis acuta generalisata*, an eruption due to upper respiratory streptococcal infection, can also present with acute onset of widespread lesions and may have eosinophils in the dermal infiltrate.⁴⁹⁹ However, the intraepidermal pustules tend to be larger, and there are more pronounced dermal infiltrates and more obvious leukocytoclastic vasculitis than would be expected in AGEP.^{500–502} The pustules of *pustular psoriasis* are usually larger and show more prominent spongiform pustulation, whereas the degrees of acanthosis in AGEP are generally less than would be expected in fully developed plaque-type psoriasis. An increase in Ki-67-positive keratinocytes is seen in both pustular psoriasis and AGEP, with no significant difference in numbers or distribution of these cells.⁵⁰³ In comparing these two dermatoses, AGEP often has eosinophils in the pustules or in the dermis, necrotic keratinocytes, a neutrophil-rich but mixed interstitial and mid-dermal infiltrate, and a lack of tortuous dilated blood vessels.⁵⁰⁴ Despite an occasional clinical resemblance to *erythema multiforme*, pustules are generally not observed in the latter disease, whereas apoptosis is usually more extensive than in lesions of AGEP. As noted previously, a resemblance has been noted between AGEP and toxic epidermal necrolysis. This has been mostly based on clinical features.^{505–507} Although one study reported a potential histopathologic resemblance as well, the photomicrographs of that case show an intraepidermal pustule with necrosis of the overlying epidermis and adjacent spongiosis – features more in keeping with AGEP – whereas other potentially differentiating features, such as the presence or absence of eosinophils, were not described.⁵⁰⁸ Infection with *Candida* or a dermatophyte could show overlapping features, but PAS or silver methenamine stains would be positive for microorganisms in those disorders.

MILIARIA CRYSTALLINA

The condition known as miliaria crystallina is associated with small, 1- to 2-mm vesicles that rupture easily (see p. 108).

Histopathology

The vesicle forms within or directly beneath the stratum corneum. It is centered on the acrosyringium.

INTRAEPIDERMAL BLISTERS

The term ‘intraepidermal blister’ refers to the formation of lesions within the malpighian layers; it does not include those vesiculobullous diseases in which the split occurs beneath the stratum corneum or in a suprabasilar position. Note, however, that biopsies from some of the diseases listed as forming subcorneal or suprabasilar blisters may sometimes show splitting within the malpighian layers. This is particularly likely in lesions of some days’ duration in which regeneration of the epidermis may alter the level of the split.

Intraepidermal blisters usually form as the outcome of spongiosis or ballooning degeneration. The primary acantholytic diseases usually form blisters that are subcorneal or suprabasilar in position, before regeneration occurs. Most of the intraepidermal blistering diseases are discussed elsewhere but, with the exception of hydroa vacciniforme (see p. 623), they are mentioned here.

SPONGIOTIC BLISTERING DISEASES

Although most of the diseases that produce the spongiotic reaction pattern (see Chapter 5) can sometimes be associated with clinically visible vesicles and even bullae, the ones most often associated with blisters are allergic contact dermatitis, nummular dermatitis, pompholyx, polymorphic light eruption (vesicular type), insect bite reactions, incontinentia pigmenti (first stage), and miliaria rubra. The presence of spongiosis adjacent to the vesicle or elsewhere in the biopsy is the clue to this group of blistering diseases. Eosinophils are prominent in the infiltrate in insect bite reactions and incontinentia pigmenti.

The bullae that sometimes form in **acrodermatitis enteropathica** (see p. 567) are intraepidermal in location. Intraepidermal or subcorneal clefting can also occur in the glucagonoma syndrome (see p. 569).

Tense bullae have been reported on the feet of a male with malignancy-associated **acrokeratosis paraneoplastica** (Bazex’s syndrome). The lesions were characterized by apoptotic basal keratinocytes and microvesicles. No mention was made of their location in the epidermis.⁵⁰⁹

Eczematous and vesiculobullous variants of **mycosis fungoides** have been reported. They are exceedingly rare. The prognosis of this variant is often poor, but in a recently reported case there was a 30-year history of the mycosis fungoides and a 25-year history of blisters.⁵¹⁰ Subepidermal blisters may also occur.

Palmoplantar pustulosis commences as a spongiotic vesicle, but pustulation rapidly ensues (see below).

PALMOPLANTAR PUSTULOSIS

Palmoplantar pustulosis is a chronic inflammatory skin disorder in which there are erythematous, scaly plaques with recurrent sterile pustules, symmetrically distributed on the palms and soles.^{511–513} Initially, only a palm or a sole may be involved.⁵¹⁴ The Koebner phenomenon is a rare manifestation.⁵¹⁵ Onset of the disease is usually between the ages of 40 and 60 years. Women are predominantly affected.⁵¹⁴ Palmoplantar pustulosis is sometimes associated with a focus of infection somewhere in the body,⁵¹⁶ although elimination of the infectious process usually has no influence on the course of the disease,^{511,517} which is usually protracted and somewhat unpredictable. A case responding to treatment of the accompanying severe periodontitis has been reported.⁵¹⁸ Another anecdotal case responded to treatment of her *Helicobacter pylori* infection.⁵¹⁹

Psoriasis is present in at least 6% of cases; some studies have shown a much greater incidence.⁵²⁰ However, unlike psoriasis, there are no clear associations with any particular HLA type.⁵²¹ There is also a difference in the surface receptors on neutrophils in the two conditions.⁵²² Both psoriasis and palmoplantar pustulosis may be precipitated by lithium.⁵²³ Both may be precipitated by the use of TNF- α inhibitors used in the treatment of various diseases.⁵²⁴ Infliximab can also worsen the disease.⁵²⁵ This may be related to the role of TNF- α in normal eccrine sweat ducts.⁵²⁵ Granulocyte colony-stimulating factor also exacerbates the disease.⁵²⁶ Furthermore, a seronegative spondyloarthropathy is sometimes present.⁵²⁷ There is also an increased incidence of osteoarthritis.⁵²⁸ An association with Sweet’s syndrome and an association with stress have been reported.^{513,529}

Other clinical findings in palmoplantar pustulosis include the presence of sternocostoclavicular ossification in 10% of cases,⁵²⁷ lytic, but sterile, bone lesions,⁵³⁰ and an increased incidence of autoantibodies to thyroid antigens^{531–533} and to gliadin.⁵³⁴ However, no increase in anti-gliadin antibodies was found in a German series of patients with this disease when compared to controls.⁵³⁵

Palmoplantar pustulosis has been regarded as a form of psoriasis, a bacterid (an inflammatory reaction at a site remote from that of a bacterial infection presumed to be of pathogenetic significance), and a distinct clinicopathological entity, probably with an immunological pathogenesis.^{536,537} The last of these theories is supported by the finding of increased numbers of Langerhans cells in active lesions⁵³¹ and increased levels of proinflammatory cytokines such as IL-6, TNF- α , and interferon- α . The IL-10 cytokine family (IL-19, IL-20, and IL-24) also plays a role in epidermal function and inflammation. They are controlled by a gene cluster on chromosome 1q31–q32. Gene polymorphisms in this cluster have been demonstrated in palmoplantar pustulosis.⁵³⁸ There is evidence that the very rare acute form of palmoplantar pustulosis, which may progress into the chronic form, is a bacterid with an associated vasculitis.⁵³⁹ It has also been linked to smoking^{532,540} and metal (jewelry) allergy.^{541,542} Up to 95% of patients are smokers at the time of onset of the disease. Approximately 40% of patients have antibodies to nicotinic acetylcholine receptors. On this basis, it has been postulated that palmoplantar pustulosis is an autoimmune disease precipitated by smoking.⁵⁴³ It has been suggested that the acrosyringium is the target for the inflammation.⁵³² Nicotine is excreted in the eccrine palmar duct.⁵⁴⁴ In contrast to psoriasis, Langerhans cells, IL-17, regulatory T cells, and CD11a-positive cells are found close to or near the acrosyringium in palmoplantar pustulosis;⁵⁴⁵ furthermore, gross cystic disease fluid protein-15 and epithelial membrane antigen, both markers of acrosyringium, line the intraepidermal vesicles in this disease.⁵⁴⁶ In summary, it appears that there is no single factor that causes palmoplantar pustulosis. It may be precipitated in patients, some of whom have a heightened production of proinflammatory cytokines, by a diverse group of antigens including nicotine, infectious agents, metals, and TNF- α antagonists. Some cases are cured by the cessation of smoking alone.⁵⁴⁴ A gluten-free diet has resulted in improvement in patients with anti gliadin antibodies, regardless of the degree of mucosal abnormalities.⁵³⁴ Other cases require topical corticosteroids, systemic retinoids, PUVA, cyclosporine,⁵⁴⁷ or methotrexate.⁵⁴⁸ One case was successfully treated with etanercept, a paradox similar to psoriasis where it can both treat and precipitate the disease.⁵⁴⁸ Ustekinumab, a monoclonal antibody directed against IL-12 and IL-23, has been used to treat this disease and may be effective in palmoplantar pustulosis due to TNF inhibitors;⁵⁴⁹ similar effectiveness has been shown with tocilizumab, a monoclonal antibody against the IL-6 receptor.⁵⁵⁰

Histopathology⁵³⁷

The earliest lesion is a spongiotic vesicle in the lower malpighian layer that contains mononuclear cells and some neutrophils.⁵¹¹ This progresses to a unilocular, well-delimited pustule within the epidermis and extending upwards to the undersurface of the stratum corneum (Fig. 6.6).⁵¹¹ There may be overlying, focal parakeratosis. In the dermis, a mixed perivascular and diffuse infiltrate of inflammatory cells is present.

Differential diagnosis

Controversy exists as to whether it is possible to differentiate pustular psoriasis and palmoplantar pustulosis on histopathological grounds.⁵⁵¹ Spongiform pustulation is often present at the upper margins of the pustule in palmoplantar pustulosis, but the focus is usually much smaller than that seen in pustular psoriasis.⁵⁵¹ Sometimes there is spongiosis without associated pustulation; this feature is not present in pustular psoriasis.⁵⁵¹ Eosinophils may be present in palmoplantar pustulosis, a finding not usually seen in pustular psoriasis.⁵³²

Immunoreactants are present in the stratum corneum in some cases of palmoplantar pustulosis.⁵⁵² Regarding the histopathologic differentiation from pompholyx, Yoon *et al.* found that loss of the granular cell layer, thinning of suprapapillary plates, eosinophils in pustules or vesicles, tortuosity of capillaries, capillaries touching the undersurface

Figure 6.6 Palmoplantar pustulosis. There is a well-delimited, unilocular pustule extending to the undersurface of the stratum corneum. (H&E)

of the epidermis, and extravasated erythrocytes were statistically significant features of palmoplantar pustulosis, and psoriasiform epidermal features also tended to favor palmoplantar pustulosis. On the other hand, pompholyx tended to have multiple foci of parakeratosis, irregular acanthosis, and thinning of rete ridges.⁵⁵³ These two disorders also show a different pattern of epithelial membrane antigen staining within the epidermis; both show staining along the edge of intraepidermal vesicles, but there is little staining of the surrounding epidermis in palmoplantar pustulosis, whereas there is strong and diffuse staining of neighboring keratinocytes in pompholyx.⁵⁵⁴

AMICROBIAL PUSTULOSIS ASSOCIATED WITH AUTOIMMUNE DISEASES

The rare disease amicrobial pustulosis associated with autoimmune diseases, known by the acronym APAD, is a chronic relapsing eruption involving predominantly the main cutaneous flexures, external auditory canal, and scalp.⁵⁵⁵ It has been reported in association with various autoimmune diseases.^{556,557} Most, if not all, cases have been in females, usually of reproductive age.⁵⁵⁸ In one case, there was associated IgA nephropathy and Sjögren's syndrome.⁵⁵⁹ Some improvement has occurred after oral zinc supplementation.⁵⁵⁶

Histopathology

There are high intraepidermal spongiform pustules in an acanthotic epidermis. There is usually overlying parakeratosis containing neutrophil debris. Exocytosis of neutrophils into the epidermis is present.⁵⁵⁵ A mixed perivascular infiltrate of neutrophils and lymphocytes, with nuclear dust, is present in the upper dermis. There is marked overexpression of Bcl-2 in lesional skin.⁵⁵⁸

EROSIVE PUSTULAR DERMATOSIS OF THE LEG

Erosive pustular dermatosis of the leg is another amicrobial pustulosis.⁵⁶⁰ It is also considered in Chapter 23 with erosive pustular dermatosis of the scalp, but because bacterial growth in that condition is almost certainly a secondary event, it could also have been included here with the other amicrobial pustuloses, as could the autoinflammatory (periodic fever) syndromes (see p. 247).

Erosive pustular dermatosis of the leg is characterized by crusted pustules and erosions forming erythematous plaques on the lower legs.

There is usually underlying chronic venous insufficiency, stasis dermatitis, and atrophy of the skin. It runs a chronic course.

Topical corticosteroids and tacrolimus have produced improvement in the lesions.⁵⁶¹

Histopathology

Intact lesions show spongiotic pustules at a high level in the epidermis.⁵⁶² They eventually become subcorneal or intracorneal in location.⁵⁶⁰ There is usually some acanthosis and a mixed dermal infiltrate of neutrophils, lymphocytes, and a few plasma cells. Erosions are common; they have a heavy mixed inflammatory cell infiltrate in the base.

VIRAL BLISTERING DISEASES

Intraepidermal vesicles are seen in herpes simplex; herpes zoster; varicella; hand, foot, and mouth disease; and some cases of milker's nodule and orf. In the case of herpes simplex, herpes zoster, and varicella, there is ballooning degeneration of keratinocytes with secondary acantholysis of cells. Multinucleate keratinocytes, some with intranuclear inclusion bodies, may also be seen. In hand, foot, and mouth disease, there is both spongiosis and intracellular edema, whereas in milker's nodule and orf there may be pronounced intracellular edema with pallor and degeneration of keratinocytes in the upper layers of the epidermis. A severe, diffuse blistering eruption has been reported in two patients with orf.⁵⁶³ Viral DNA was detected in one case in the inciting orf lesion, but not in blistered skin, ruling out disseminated orf infection as a cause of the blisters. Both cases were characterized by subepidermal blisters with a mixed inflammatory cell infiltrate in the base that included neutrophils and eosinophils. IgG and C3 were deposited in a linear manner at the basement membrane zone of perilesional skin, and indirect IF revealed circulating anti-basement membrane IgG that bound to the dermal side of salt-split skin.⁵⁶³ Milker's nodule and orf are discussed in Chapter 26.

EPIDERMOLYSIS BULLOSA SIMPLEX (LOCALIZED TYPE)

In the localized type of epidermolysis bullosa simplex, formerly known as the Weber–Cockayne type (see p. 157), the split is usually in the mid or upper layers of the epidermis, although in induced blisters the split develops in the basal layer. An occasional dyskeratotic cell may be present in the epidermis.

FRICTION BLISTER

Friction blisters are produced at sites where the epidermis is thick and firmly attached to the underlying dermis, as on the palms, soles, heels, and the back of the fingers.

Histopathology

The blister usually forms just beneath the stratum granulosum. The keratinocytes in the base of the blister show variable edema and pallor and even degenerative changes.

SUPRABASILAR BLISTERS

The suprabasilar blistering diseases – pemphigus vulgaris, pemphigus vegetans, Hailey–Hailey disease (familial benign chronic pemphigus), Darier's disease, Grover's disease (transient acantholytic dermatosis), and acantholytic solar keratosis – all result from acantholysis. Supra-

basal acantholysis has been reported in one case of necrolytic migratory erythema. It may sometimes be seen in paraneoplastic pemphigus. In blisters of some days' duration, the split may be present at a higher level within the epidermis as a result of epidermal growth.

PEMPHIGUS VULGARIS

Pemphigus vulgaris (OMIM 169610) is a rare vesiculobullous condition that accounts for approximately 80% of all cases of pemphigus.^{564–569} Its incidence is approximately 0.1–1.0 per 100,000/year.^{570–572} There is a slight female predominance in most countries, but not in others.^{573,574} It is characterized by the production of autoantibodies to the epithelial adhesion protein desmoglein 3 (dsg3).⁵⁷⁵ The initial presentation is often with oral blisters,^{576,577} ulcers, and erosions, which are followed within weeks to months by the development of cutaneous lesions.⁴⁵ Nail involvement is relatively rare.^{578–580} Skin lesions take the form of flaccid blisters on a normal or erythematous base; there is a predilection for the trunk, groins, axillae, scalp, face, and pressure points.⁴⁵ Penile involvement is rare,⁵⁸¹ and rarer still is its presentation as the first manifestation of the disease.⁵⁸² Sometimes lesions are localized to one body site, such as the nose and cheeks.⁵⁸³ The blisters break easily, giving eroded and crusted areas. Application of pressure to a blister leads to its extension (Nikolsky's sign or the Asboe–Hansen sign).^{564,584} Burning and itching may be present.⁵⁷⁶ The lesions generally heal without scarring.⁴⁵

In addition to oral lesions, which eventually develop in 75–90% of cases,^{585–587} other mucosal surfaces may be involved.⁵⁸⁸ These include the conjunctiva,^{589–591} pharynx,⁵⁹² and larynx,^{218,593} and, rarely, the esophagus,^{594–598} urethra, anorectum, vulva, vagina, and cervix.^{599–602} In a study from Japan, 75% of patients presented with involvement of the oral mucosa.⁶⁰³ Mucosal lesions are less common in some countries than in others.⁶⁰⁴ The reason for this is not known.

Rare clinical presentations include localized lesions; bilateral foot ulcers;⁶⁰⁵ lesions limited to the surgical area after mastectomy;⁶⁰⁶ localization to a melanocytic nevus;⁶⁰⁷ generalization of oral disease following varicella infection;⁶⁰⁸ the development of lesions in childhood,^{609–611} in siblings,^{612–614} or in a familial setting;^{615,616} the development of transient blisters in a neonate whose mother has pemphigus or is asymptomatic, due to the transplacental passage of dsg3 antibodies from the mother;^{617–627} the development of nodular,⁶²⁸ vegetative,⁶²⁹ or acanthosis nigricans-like lesions;⁶³⁰ and the coexistence of pemphigus vulgaris with bullous pemphigoid.^{631–633} Rarely, the clinical and histological features of pemphigus vulgaris may change to those of pemphigus foliaceus;^{634,635} the antibody profile also changes.^{636–639} Cases with overlap features also occur.^{82,640} Several cases of endemic pemphigus vulgaris have been reported from regions with endemic pemphigus foliaceus.⁶⁴¹ Internal cancer,^{642,643} vulvar squamous cell carcinoma,⁶⁴⁴ multiple myeloma,⁶⁴⁵ Castleman's disease,^{646,647} 1p36 deletion syndrome,⁶⁴⁸ thymoma,^{91,642,649,650} myasthenia gravis,⁶⁵¹ minimal change nephropathy,⁶⁵² localized scleroderma,⁶⁵³ Graves' disease,⁶⁵⁴ hyperprolactinemia,⁶⁵⁵ silicosis,⁶⁵⁶ SLE,^{657,658} mixed connective tissue disease,⁶⁵⁹ dermatomyositis,⁶⁶⁰ antiphospholipid antibodies,⁶⁶¹ oral submucosal fibrosis,⁶⁶² and oral herpes simplex or HIV infection^{663–665} are rare clinical associations. There is an increased susceptibility to the development of autoimmune diseases in the family members of patients with pemphigus vulgaris.^{666,667} Several HLA types (class II) are prevalent in patients with pemphigus vulgaris.^{668–672} The HLA haplotypes DRB1*0402, DQB1*0302, DRB1*1401, and DQB1*0503 appear to confer a significant disease risk across a wide range of populations.⁵⁷⁵ Another genotype, HLA-E*0103X, has also been found to be a marker for genetic risk in pemphigus vulgaris.⁶⁷³ Polymorphisms in the *PTPN22* gene, a candidate gene for autoimmune diseases, have not been detected in pemphigus vulgaris.⁶⁷⁴

The prognosis has improved considerably in recent years, although the mortality is still 5–19%; deaths often result from infections

complicating corticosteroid therapy⁶⁷⁵⁻⁶⁷⁷ and biochemical abnormalities associated with extensive disease.⁶⁷⁸ In one study, complete and long-lasting remissions were induced in 25%, 50%, and 75% of patients 2, 5, and 10 years, respectively, after diagnosis.⁶⁷⁹

Etiology and pathogenesis

The antibodies in pemphigus vulgaris are directed against *dsg3*, a 130-kDa polypeptide that, like the pemphigus foliaceus antigen (*dsg1*), is a member of the desmoglein subfamily of the cadherin supergene family.^{680,681} Genetic variations in *DSG3*, the gene controlling *dsg3* on chromosome 18q12, appear to be an additive risk factor predisposing to pemphigus vulgaris.⁵⁷⁵ *Dsg3* is localized to the desmosomes of keratinocytes, particularly the extracellular domain.^{216,682,683} Epitope mapping suggests that a segment containing amino-terminal residues 1–161 of *dsg3* contains the critical antigens recognized by the autoantibodies in pemphigus vulgaris sera.⁶⁸⁴ This segment is considered to include structures essential for cell–cell adhesion.⁶⁸⁴ The cytoplasmic ‘tail’ of the pemphigus vulgaris antigen, like other desmogleins, binds to the plakoglobin inside keratinocytes.^{680,685-687} Plakoglobin delocalization from the nucleus may play a role in the production of acantholysis (discussed later).^{688,689} More than 50% of sera from patients with pemphigus vulgaris also contain autoantibodies against *dsg1*. These antibodies also appear to be pathogenic.⁶⁹⁰ There is a shift over time in the profile of anti-desmoglein antibodies in pemphigus vulgaris.^{691,692} The antibodies against both *dsg1* and *dsg3* have predominant IgG4 subclass specificity.^{690,693-695} Antibodies in the IgA and IgE class have also been detected.^{696,697} The majority of patients with mucosa-dominant disease have antibodies only against *dsg3*,⁶⁹⁸ but a significant number also have antibodies to *dsg1*.⁶⁹⁹ The development of antibodies to *dsg1* in some patients with *dsg3*-related mucosal disease is sometimes accompanied by changes in the clinical expression of the disease, such as the development of generalized cutaneous lesions.⁷⁰⁰⁻⁷⁰⁵ Conversely, lesions limited to the skin may occur in the presence of predominant *dsg1* autoantibodies and weaker levels of *dsg3* autoantibodies, but antibody levels are not the complete explanation for this phenomenon.^{706,707} Anti-desmoplakin antibodies, which are usually found in paraneoplastic pemphigus, have also been reported in patients with mucosal dominant pemphigus vulgaris, who also had *dsg3* autoantibodies.⁷⁰⁸⁻⁷¹⁰ Although it has been thought that typical pemphigus does not have autoantibodies to the desmocollins,⁷¹¹ studies by Mao *et al.* have shown that at least a subset of patients with identical clinical presentations have desmocollin 3 as the pathogenic autoantigen. Among other findings, IgG from these patients incubated with human keratinocytes causes loss of intercellular adhesion, and prior adsorption with recombinant desmocollin 3 prevents this effect.¹⁶ In pemphigus vulgaris, the antibodies produced by circulating B cells tend to bind preferentially to desmosomes in the lower epidermis, reflecting differences in the relative expression of the different cadherins in different levels of the epidermis.^{216,712} This antibody binding may be followed by internalization of some desmosomes.⁷¹³ Antibodies will only cause cell separation (acantholysis) where the antigen is the principal adhesion molecule and others are unable to compensate.⁷¹⁴ Cholinergic receptors on keratinocytes also play a role in cell adhesion.^{715,716} Antibodies to the acetylcholine receptors α -9 acetylcholine receptor and pemphaxin are present in humans with pemphigus vulgaris.⁷¹⁷ Autoantibodies to these receptors can induce clinical features resembling pemphigus in *dsg3*-deficient knockout mice.^{718,719} Cholinergic agonists ameliorate acantholysis in mice.⁷²⁰ Antibody levels to the acetylcholine receptor are somewhat elevated in pemphigus vulgaris patients and appear to correlate with disease activity.⁷²¹ There is also upregulation of P-cadherin expression in lesional skin.⁷²² E-cadherin autoantibodies have also been found in the sera of patients.¹⁴ Another protein involved in cellular adhesion is focal adhesion kinase (p125^{fa}). Its upregulation in lesional skin may be a reactive or reparative response to acantholysis.⁷²³ Using

a passive transfer mouse model of pemphigus vulgaris, Espana *et al.* found that neural nitric oxide synthase (nNOS) may be involved in epidermal growth factor (EGF) receptor-mediated acantholysis via upregulation of Rous sarcoma kinase (Src), mammalian target of rapamycin (mTOR), and focal adhesion kinase, with eventual upregulation of caspase-9 and caspase-3.⁷²⁴ The desmosomal damage and consequent acantholysis may follow the activation of complement^{130,147,725,726} or local stimulation of the plasminogen–plasmin system, independent of complement (see later).⁷²⁷⁻⁷²⁹ However, studies using plasminogen activator knockout mice suggest that this system is not necessary for blister formation.¹⁴⁸ Experimental evidence suggests that antibodies may eventually generate desmosomes lacking *dsg3*, resulting in acantholysis.⁷³⁰ Other mechanisms involved in acantholysis include the release of keratinocyte-derived cytokines such as IL-1 and TNF- α .⁷³¹

These traditional views that acantholysis results from a defect in desmosomes resulting from antibody/complement deposition have been challenged in recent years by several groups.^{732,733} The binding of antibodies leads to intracellular events that precede the acantholysis. Bystryn and Grando believe that keratinocytes separate because cytoskeletal collapse results in the inability of desmosomes to hold cells together any longer, not because of a defect in the desmosomes.⁷³² The shrinkage is limited to basal cells because they are less rigid and shrink easily. It has been suggested subsequently that this cytoskeletal collapse is due to keratin intermediate filament retraction linked to plakoglobin-dependent signaling⁷³³ or nuclear delocalization.⁶⁸⁸ The entire process of antibody binding to keratinocytes, keratin retraction, cell shrinkage, and eventual acantholysis occurs very rapidly. There may be signaling events other than plakoglobin, such as heat shock protein, that trigger this cytoskeletal collapse.⁷³⁴ The importance of intracellular signaling cascades in producing blisters in pemphigus vulgaris has been confirmed in an animal model.⁷³⁵ Other studies indicate that reorganization of the actin cytoskeleton is an important factor in pemphigus vulgaris IgG-related dissociation among keratinocytes.⁷³⁶

Activated mononuclear cells are present in lesional skin and may contribute to the pathogenesis.⁷³⁷ Autoreactive T lymphocytes that respond to epitopes located on *dsg3* have been identified, confirming a role for cell-mediated as well as humoral responses in pemphigus vulgaris.^{738,739} This Th2 response directs autoantibody production.⁷⁴⁰ T cells that react against *dsg1* are sometimes present.⁷⁴¹ Various inflammatory mediators have been isolated from blister fluid, and these presumably have a role in eliciting the accompanying inflammatory response.⁷⁴² Osteopontin may be one of the cytokines that drives this immune response.⁷⁴³ What stimulates the formation of antibodies is unknown, although minor trauma,^{44,744,745} surgery,⁷⁴⁶ ionizing radiation,⁷⁴⁷ thermal burns,⁷⁴⁸ PUVA therapy,⁷⁴⁹ viral infection,^{750,751} and exposure to chemicals⁷⁵² have occasionally been documented prior to the onset of the disease. Cutaneous lesions limited to a radiation portal have been reported.^{753,754} Anti-desmoglein autoantibodies are sometimes found in patients with no bullous disease. For example, they have been found in some patients with silicosis⁷⁵⁵ and in relatives of patients with pemphigus vulgaris.⁷⁵⁶ The term ‘contact pemphigus’ has been used for cases that have followed contact with chemicals, usually pesticides.⁷⁵⁷⁻⁷⁶⁰ Pemphigus foliaceus has been found in dogs that were treated with the topical flea preventative metaflumizone–amitraz.⁷⁶¹ Contact pemphigus has also followed the application of imiquimod.⁷⁶² Smoking seems to have a protective function.⁷⁶³ There are also cases in which rifampin (rifampicin),⁷⁶⁴ norfloxacin,⁷⁶⁵ ciprofloxacin,⁷⁶⁶ ampicillin,⁷⁶⁷ penicillin,^{768,769} IL-2,⁷⁷⁰ captopril,^{771,772} fosinopril,⁷⁷³ enalapril,⁷⁷⁴ quinapril,¹¹⁵ cilazapril,⁷⁷⁵ typhoid, anthrax, tetanus and diphtheria⁷⁷⁶ and influenza vaccinations,⁷⁷⁷⁻⁷⁷⁹ diclofenac,⁷⁸⁰ ketoprofen,⁷⁸¹ penicillamine,⁷⁸² hydroxychloroquine,⁷⁸³ dipyrone,⁷⁸⁴ nifedipine,⁷⁸⁵ cocaine snorting,⁷⁸⁶ amoxicillin/clavulanic acid,⁷⁸⁷ and possibly other drugs,^{119,788} have precipitated pemphigus vulgaris. Drugs with thiol groups have a particular

capacity to precipitate or exacerbate pemphigus.⁷⁸⁹ Despite this long list of drugs, a recent study concluded that drugs are a rare precipitating factor.⁷⁹⁰ Incidental acantholysis has been found in two biopsies from a patient on enalapril who had no clinical features of pemphigus vulgaris.⁷⁹¹ Carbamazepine can result in the production of antibodies to dsg1 and dsg3 without producing lesions.⁷⁹²

The role of various foods in the precipitation of pemphigus has been studied.^{793,794} Possible candidates include thiol-containing foods (garlic, onion, leek, and shallots), thiocyanates (mustards), phenols (artificial sweeteners, preservatives, and colorings), and tannins (certain fruits).^{794,795}

The finding of HHV-8 DNA sequences in lesional skin may indicate trophism for pemphigus lesions rather than an etiological role.^{796,797}

The desmoglein ELISA was positive in all 29 cases of pemphigus vulgaris in one series. It was superior to indirect IF as a diagnostic tool.⁷⁹⁸ Other studies have confirmed the reliability of the ELISA test.^{799,800} It may be used to monitor disease activity⁸⁰¹ because the titer of circulating antibodies tends to parallel this activity.^{802–806} Nevertheless, circulating anti-Dsg autoantibodies are still found in some pemphigus patients in remission, particularly if their titers during the active phases of the disease were high.⁸⁰⁷

Treatment

Now that a consensus statement has been produced defining aspects of the disease, including severity and end points, comparative treatment studies can be undertaken.⁸⁰⁸ More trials are needed to assess some of the newer therapies.⁸⁰⁹ Therapies that have been used include systemic corticosteroids, usually in a high dose; a pulse protocol using intravenous betamethasone and oral prednisone;⁸¹⁰ cyclophosphamide;⁸¹¹ azathioprine; prednisolone alone or combined with azathioprine, cyclophosphamide, or mycophenolate mofetil;⁸¹² dapsone;⁸¹³ high-dose intravenous immunoglobulin, alone or as a steroid-sparing agent;^{814–817} plasmapheresis; protein A immunoadsorption combined with other therapies;^{717,818–822} gold;⁸²³ rituximab;^{824–828} etanercept;⁸²⁹ thalidomide;⁸³⁰ topical tacrolimus combined with cyclophosphamide and prednisolone;⁸³¹ and EGF in 0.1% silver sulfadiazine cream.⁸³²

Histopathology

Established lesions of pemphigus vulgaris are suprabasal bullae with acantholysis (Fig. 6.7). The clefting may extend down adnexal structures. The basal cells lose their intercellular bridges, but they remain attached to the dermis, giving a 'tombstone appearance'.⁸³³ The blister cavity usually contains a few acantholytic cells that often show degenerative changes. Occasionally, a few eosinophils or neutrophils are present in the cavity.⁴⁵

The earliest changes in pemphigus vulgaris consist of edema and disappearance of the intercellular bridges of keratinocytes in the lower epidermis (Fig. 6.8). This leads to acantholysis and subsequent suprabasal blisters. These changes may also occur at an early stage in hair follicles.⁸³⁴ Eosinophilic spongiosis and subepidermal splitting are two rare presentations of pemphigus vulgaris (see Fig. 6.7C).⁸³⁵ Vegetative lesions show epidermal hyperplasia but a paucity of eosinophils, in contrast to pemphigus vegetans. Acanthomas resembling seborrheic keratosis may form at the sites of previous blisters.⁸³⁶

Dermal changes are of little significance. There is usually a mild, superficial, mixed inflammatory cell infiltrate that usually includes scattered eosinophils. There are no histological features that differentiate drug-associated pemphigus vulgaris from idiopathic cases.⁸³⁷

Immunostaining with the monoclonal antibody 32-2B, which detects desmogleins 1 and 3, can be used in many cases to distinguish drug-induced pemphigus from idiopathic pemphigus.⁸³⁸ Whereas a patchy pattern of staining was observed in idiopathic pemphigus, the staining was more often 'normal' in drug-induced cases, although patchy staining was found in 30% of cases (70% sensitivity).⁸³⁸

Figure 6.8 Pemphigus vulgaris. The earliest changes are intercellular edema and disappearance of the intercellular bridges in the lower epidermis. (H&E)

Figure 6.9 Pemphigus vulgaris. IgG is deposited in the intercellular regions of the epidermis. The upper layers are spared. (Direct immunofluorescence)

Direct IF usually demonstrates IgG in the intercellular regions of the epidermis in and around the affected parts of the skin or mucous membrane (**Fig. 6.9**).^{839,840} IgG1 and IgG4 are the subclasses of IgG found most commonly in patients with active lesions;⁸⁴¹ C3, IgM, and IgA are present less frequently.^{839,842} Direct IF can also be performed on plucked anagen hair.^{843,844} Intercellular staining is seen between cells of the outer root sheath.⁸⁴³ Patients in clinical remission, who have positive direct IF on a skin biopsy, are more likely to relapse than those with negative immunofluorescence findings.^{845–847} Circulating intercellular antibodies are present in 80–90% of patients with pemphigus vulgaris, although they may be absent in early cases.^{209,848,849} Their demonstration depends to some extent on the substrate used; monkey esophagus gives a higher yield of positive results than guinea pig esophagus or human skin.^{850–852} Pemphigus-like antibodies have also been reported in a wide range of inflammatory dermatoses, as well as following burns.^{848,853}

Cytology preparations obtained from smears of bullae show acantholytic cells with ameboid cytoplasmic projections, as well as eosinophils, basophils, and lymphocytes, some of which have abnormal nuclear contours. Older bullae possess dysplastic epithelial cells with high nuclear:cytoplasmic ratios and prominent nucleoli.⁸⁵⁴ Acantholytic cells can also be appreciated with reflectance confocal microscopy.⁸⁵⁵

Electron microscopy⁴⁵

There is dissolution of the intercellular attachments, leading to a widening of the intercellular spaces and eventual separation of the desmosomal attachment plaques.⁸⁵⁶ As acantholysis progresses, the desmosomes gradually disappear, followed by retraction of the tonofilaments to the perinuclear area. The keratinocytes often develop numerous, interdigitating processes. Immunoelectron microscopy shows that the immunoglobulins are deposited on the surface of the epidermal cells in a discontinuous globular pattern in the region of the intercellular domains of desmosomes.⁸⁵⁷

Differential diagnosis

Pemphigus vulgaris can be potentially confused with other acantholytic disorders, particularly *Hailey–Hailey disease* (familial benign chronic pemphigus), an inherited acantholytic disorder, and a similar but localized disorder that appears to be acquired, *acantholytic dermatosis of the genitocrural region*. However, those conditions usually show much more extensive suprabasilar acantholysis, with separation of keratinocytes in the spinous layer producing the appearance of a ‘dilapidated brick wall’. Some dyskeratosis can be seen in Hailey–Hailey disease – a feature not often seen in pemphigus. Importantly, the acantholysis in Hailey–Hailey disease ‘respects’ the hair follicles; that is, follicular epithelia in acantholytic lesions tend to be spared. This is not the case in pemphigus. Dermal infiltrates containing eosinophils are common in pemphigus, and eosinophilic spongiosis may occur in early lesions. This cell type is less common in Hailey–Hailey disease; although eosinophils can occasionally be seen, Hailey–Hailey disease is not associated with eosinophilic spongiosis. Examples of focal acantholytic dyskeratosis, particularly *transient acantholytic dermatosis (Grover’s disease)*, can have a pemphigus vulgaris-like configuration, but often some dyskeratosis can be identified. *Actinic keratoses with marked acantholysis* might occasionally mimic a lesion of pemphigus vulgaris, but some degree of basilar keratinocyte atypia is usually present, and the clinical presentation would be quite different from that of pemphigus. Immunofluorescent studies would be definitive because among these conditions, only pemphigus shows positive intercellular fluorescence. Although a characteristic feature of paraneoplastic pemphigus is positive indirect IF using murine bladder epithelium (see later), some cases of non-neoplastic pemphigus vulgaris and pemphigus foliaceus are also positive using this substrate.²⁰⁹

PEMPHIGUS VEGETANS

Pemphigus vegetans is a rare variant of pemphigus vulgaris⁴³ that differs from it by the presence of vegetating erosions, primarily affecting flexural areas.^{565,858–860} Two variants of pemphigus vegetans have been recognized.⁸⁵⁸ In the *Neumann type*, the initial lesions are vesicular and erosive, resembling pemphigus vulgaris, but the lesions progressively evolve into vegetating plaques. The less common *Hallopeau type* commences with pustular lesions and has a relatively benign course with few, if any, relapses.^{861–863}

Oral lesions are almost invariably present in pemphigus vegetans, and these may be the presenting or dominant feature.^{864–866} Some of these cases may represent **pyodermitis–pyostomatitis vegetans (pyoderma vegetans, pyostomatitis vegetans; PPV)**, a condition that has often been confused with pemphigus vegetans.⁸⁶⁷ In PPV, annular pustular lesions on the skin may precede, accompany, or follow the usually extensive vegetating oral lesions.^{867–869} Most cases are associated with inflammatory bowel disease, particularly ulcerative colitis.^{870,871} The bowel disease usually precedes the oral lesions by months or years.⁸⁷² A patient with Crohn’s disease and pyostomatitis vegetans of the mouth and vulvoperineal region was successfully treated with a combination of infliximab and methotrexate.⁸⁷³ Topical clobetasol was

used in another patient.⁸⁷⁴ Cyclosporine was effective in a further case.⁸⁷⁵

Sometimes the surface of the tongue in pemphigus vegetans assumes a cerebriform pattern.⁸⁷⁶ Similar thickening of the epidermis of the scalp may rarely lead to the clinical picture of cutis verticis gyrata.⁸⁷⁶ Localization to the vulva and to the scalp has been reported.^{877,878} Another clinical feature is the frequent presence of eosinophilia in the peripheral blood.⁸⁵⁸ Cases induced by the ingestion of the drugs captopril and enalapril and by the intranasal use of heroin and cocaine have been reported.⁸⁷⁹⁻⁸⁸³ Its association with HIV infection and gastric cancer may have been fortuitous.^{884,885}

Immunological studies⁸⁸⁶ provide further evidence for the close relationship between pemphigus vegetans and pemphigus vulgaris.^{887,888} Circulating antibodies have been found in patients with pemphigus vegetans of the Neumann type that precipitate with the 130- and 85-kDa polypeptides of the pemphigus vulgaris antigen (dsg3), but there appear to be additional antibodies directed against as yet uncharacterized antigens.⁸⁸⁶ In the Hallopeau type, antibodies to dsg3 have been detected.^{889,890} The antibodies appear to belong to the IgG2 and IgG4 subclass, with strong complement fixation.⁸⁸⁹ IgA antibodies were also present in one case.⁸⁹⁰ The finding of circulating autoantibodies to the bullous pemphigoid antigen (BP230) in a patient with pyodermitis-pyostomatitis probably represented an epiphenomenon.⁸⁹¹

Treatment is usually with corticosteroids, but an additional immunosuppressive agent such as dapsone or azathioprine is often required. Hallopeau patients usually require lower doses of corticosteroids compared to patients with the Neumann type and have fewer relapses.⁸⁶⁶

Histopathology^{858,876,886}

In the early pustular lesions of the *Hallopeau type*, the appearances resemble those of eosinophilic spongiosis with transmigration of eosinophils into the epidermis and the formation of spongiotic microvesicles and eosinophilic microabscesses.⁸⁶² Charcot-Leyden crystals have been seen within these microabscesses.⁸⁹² Sporadic acantholytic cells may be present, although they are not usually seen in Tzanck smears prepared from the pustules.⁸⁷⁶

In early lesions of the *Neumann type*, there are intraepidermal vesicles with suprabasal acantholysis but no eosinophilic microabscesses.

The vegetative lesions of both types of pemphigus vegetans are similar, with hyperkeratosis, some papillomatosis, and prominent acanthosis with downward proliferation of the rete ridges (Fig. 6.10). There are suprabasal lacunae containing some eosinophils. A few acantholytic cells may be present, particularly in the Neumann type.

In both types of pemphigus vegetans, the upper dermis contains a heavy infiltrate of lymphocytes and eosinophils, together with some neutrophils. There may be edema of the papillary dermis.

The direct IF findings in pemphigus vegetans are similar to those in pemphigus vulgaris with the intercellular deposition of IgG and C3.⁸⁹³ Circulating antibodies to the intercellular region are usually detectable by indirect IF.

Electron microscopy^{893,894}

There is a reduction in tonofilaments and desmosomes in keratinocytes in skin adjoining the lesion; only rare desmosomes are found in affected skin.⁸⁹⁴ Migration of eosinophils into the epidermis through a damaged basement membrane is frequently observed.

Differential diagnosis

The histological features of PPV show some similarities to pemphigus vegetans. There are intraepithelial and subepithelial microabscesses with an admixture of neutrophils and eosinophils (Fig. 6.11).⁸⁶⁷ There is a moderately heavy, mixed inflammatory cell infiltrate in the underlying dermis. The lesions are usually more inflammatory than the lesions of pemphigus vegetans. Epithelial hyperplasia is variable and

Figure 6.10 Pemphigus vegetans. Suprabasal clefts containing eosinophils are present in the markedly acanthotic epidermis. (H&E)

Figure 6.11 Pyoderma vegetans in a patient with inflammatory bowel disease. There are intraepidermal pustules with many eosinophils and epidermal hyperplasia. (H&E)

usually more marked in oral lesions. Acantholysis is focal and never severe.⁸⁶⁷ Direct IF is negative, if misdiagnosed cases of pemphigus vegetans are excluded. However, there is a report of two cases presenting clinically as PPV, associated with inflammatory bowel disease, in which direct IF showed intercellular IgA deposition.³⁰⁶ It remains to be determined whether other cases presenting as PPV might also show IgA deposits.

PARANEOPLASTIC PEMPHIGUS

Paraneoplastic pemphigus (see p. 167) has polymorphous skin lesions with features of both erythema multiforme and pemphigus vulgaris clinically and histologically. Rarely, lesions may resemble bullous pemphigoid. A lichenoid tissue reaction is usually present.

HAILEY–HAILEY DISEASE

Hailey–Hailey disease (familial benign chronic pemphigus) is an uncommon genodermatosis with recurrent, erythematous, vesicular plaques that progress to small flaccid bullae with subsequent rupture and crusting. This condition is discussed on page 308.

Histopathology

Early lesions show suprabasilar clefting with acantholytic cells lining and within the clefts. Widespread partial acantholysis at different levels of the epidermis gives rise to the ‘dilapidated brick wall’ appearance that is so characteristic of the disease. In contrast to Darier’s disease, corps ronds are infrequent and grains are rare. Pemphigus vulgaris usually has less acantholysis and more cells showing pronounced dyskeratosis than Hailey–Hailey disease. Direct IF is negative.

DARIER’S DISEASE

Darier’s disease is an autosomal dominant genodermatosis with greasy, crusted papules and papulovesicles, mainly in the seborrheic areas of the head, neck, and trunk. It is characterized by the minor tissue reaction pattern known as acantholytic dyskeratosis; it is discussed in Chapter 9.

Histopathology

The papulovesicles of Darier’s disease show suprabasilar clefting with acantholysis and dyskeratotic cells in the form of corps ronds and grains (Fig. 6.12). There is an overlying keratin plug composed of orthokeratotic and parakeratotic material.

Darier’s disease shows more dyskeratosis than pemphigus vulgaris and less acantholysis than Hailey–Hailey disease.

GROVER’S DISEASE

Grover’s disease, also referred to as transient acantholytic dermatosis, is characterized by the sudden onset of small, sometimes crusted, erythematous papules and papulovesicles, particularly on the upper part of the trunk. Like Darier’s disease, it shows acantholytic dyskeratosis; it is discussed in Chapter 9.

Histopathology

Five histological patterns may be seen in Grover’s disease: the Darier-like pattern, the Hailey–Hailey-like pattern, the pemphigus vulgaris-like pattern, the pemphigus foliaceus-like pattern, and the spongiotic pattern. Subtle histopathological features may allow a lesion of Grover’s disease to be distinguished from the three diseases that Grover’s

Figure 6.12 Bullous lesion of Darier’s disease. Corps ronds and grains are present at the roof of a suprabasilar separation.

disease may resemble microscopically. Lesions of Grover’s disease usually have a much thinner keratin plug than those in Darier’s disease. The size of an individual lesion and the extent of the acantholysis are usually less in Grover’s disease than in either Hailey–Hailey disease or pemphigus vulgaris. Furthermore, the pemphigus vulgaris-like lesions of Grover’s disease sometimes involve the epidermis adjacent to a hair follicle, in contrast to the random distribution and the more extensive lesions of pemphigus vulgaris.

ACANTHOLYTIC SOLAR KERATOSIS

Acantholytic solar keratoses are not always clinically distinct from other types of solar keratosis; they may often resemble a superficial basal cell carcinoma clinically.

Histopathology

Acantholytic solar keratoses are characterized by suprabasilar clefting with acantholytic cells both in the cleft and in its margins. Atypical (dysplastic) keratinocytes are also present. The underlying dermis shows variable solar elastosis. The presence of dysplastic epithelial cells distinguishes acantholytic solar keratosis from the other suprabasilar diseases.

SUBEPIDERMAL BLISTERS – A CLASSIFICATION

As stated in the introduction, the classification of the subepidermal blistering diseases is usually based on the pattern of inflammation in the underlying dermis.⁸⁹⁵ Some overlap occurs between the various categories, particularly with subepidermal vesiculobullous diseases in which neutrophils or eosinophils are the predominant cell in the dermal infiltrate.

The use of special techniques – such as electron microscopy, immunoelectron microscopy, direct IF using salt-split skin, and immunoperoxidase techniques using monoclonal antibodies directed against various components of the basement membrane zone – has allowed many of the subepidermal blistering diseases to be characterized, in recent times, on the basis of the anatomical level of the split within the basement membrane zone. Currently, these techniques have little practical application in most laboratories; in routine practice, the

Figure 6.13 Schematic representation of the basement membrane zone (not to scale).

nature of the dermal infiltrate is used to distinguish the various subepidermal blistering diseases.

Some knowledge of the basement membrane zone and the various antigens associated with it is required for a proper understanding of the subepidermal blistering diseases.

The epidermal basement membrane

Basement membranes are thin, extracellular matrices that separate epithelia and endothelium from their underlying connective tissue.⁸⁹⁶⁻⁸⁹⁹ In the skin, basement membranes are found at the dermoepidermal junction, in the walls of blood vessels and surrounding the various adnexal structures.⁸⁹⁶ The following discussion relates to the epidermal basement membrane, which has four major structural components: proceeding from the epidermis to the dermis, they are the basal cell plasma membrane, the lamina lucida, the lamina densa, and the sublamina densa zone including the anchoring fibrils (Fig. 6.13).^{897,898} In addition to these structural components, there are numerous antigenic epitopes within this region.⁹⁰⁰⁻⁹⁰² Much of our knowledge about the basement membrane has been gained in recent times; it now appears that the PAS-positive basement membrane, visualized by light microscopists for decades, encompasses more than the true basement membrane.⁸⁹⁷

It should also be noted that there are structural and functional changes in the various components of this region with aging, probably giving a less effective epidermal anchoring system.⁹⁰³

Plasma membrane

The plasma membrane incorporates the hemidesmosomes, which are studded along the basal surface of the keratinocytes.⁸⁹⁷ Tonofilaments, composed of the intermediate keratin filaments K5 and K14, insert into the hemidesmosomes. Small anchoring filaments extend between the plasma membrane and the underlying lamina densa,⁸⁹⁸ bridging the lamina lucida. The hemidesmosomes contain the major 230-kDa bullous pemphigoid antigen (BPAG1), $\alpha_6\beta_4$ integrin, and the minor (180-kDa) bullous pemphigoid antigen (BPAG2). The extracellular domains of $\alpha_6\beta_4$ integrin (a receptor for extracellular matrix molecules) and BPAG2 extend into the lamina lucida at the site where anchoring filaments are located.⁹⁰⁴ Their interaction is necessary for the stabilization of the hemidesmosome structure.⁹⁰⁵ $\alpha_6\beta_4$ integrin is able to transduce signals from the extracellular matrix to the interior

of the cell.⁹⁰⁶ The 97-kDa antigen, autoantibodies to which are found in some patients with linear IgA bullous dermatosis, is a degradation product of BP180, one of the bullous pemphigoid antigens.

Lamina lucida

The lamina lucida is a relatively electron-lucent zone, 20–40 nm in thickness, which is contiguous with the plasma membrane of the overlying basal keratinocytes.⁹⁰⁷ The lamina lucida is the weakest link in the dermoepidermal junction, and it represents a plane that is easily severed.⁸⁹⁸ The anchoring filaments bridge the lamina lucida and insert into the lamina densa. It is possible that some filaments pass through the lamina densa and bind directly to anchoring fibrils in the sublamina densa region.⁹⁰⁴ There are multiple antigens associated with the lamina lucida, particularly the anchoring filaments. They include laminin 5, laminin 6, uncein, laminin 1, nidogen (which connects laminin to type IV collagen in the lamina densa), and epiligrin.^{900,904,908-910} Laminin 5 is a heterotrimeric protein consisting of three polypeptide chains, α_3 , β_3 , and γ_2 , each encoded by a distinct gene – *LAMA3*, *LAMB3*, and *LAMC2*, respectively.⁹¹¹ When antibodies to laminin 5 are injected into adult mice, subepidermal blisters result.¹⁸ Epiligrin, the antigen recognized in one form of mucous membrane pemphigoid, is the α_3 subunit of laminin 5.^{912,913} It has been renamed laminin 332. Epiligrin (laminin 332) was once thought to be in the lower lamina lucida, possibly at a lower level than the antigenic activity of other forms of laminin 5. Degradation of laminin 332 by plasmin impairs basement membrane assembly and epidermal differentiation. This may be an important mechanism of the basement membrane damage that occurs in sun-exposed skin.⁹¹⁴ Uncein is absent from nearly all cases of junctional epidermolysis bullosa regardless of disease subtype,⁹¹⁰ whereas laminin 5 is feebly expressed in all cases of the Herlitz subtype of junctional epidermolysis bullosa and 50% of the other subtypes. Autoantibodies to uncein appear to characterize an exceedingly rare subepidermal blistering disease.⁹¹⁵ Fibronectin, which is not confined to a single ultrastructural region, binds to collagen and other components of this zone.⁹¹⁶

Lamina densa

The lamina densa, which is of epidermal origin, is approximately 30–60 nm in width.⁸⁹⁸ It is present just beneath the lamina lucida, and it rests on the underlying dermal connective tissue.⁹⁰⁷ The lamina densa

has been referred to in the past as the basal lamina, but this term has also been applied to the lamina lucida and the lamina densa together.^{898,900,917} The lamina densa consists of a lattice network of structural proteins. The main component is type IV collagen, which is thought to provide the basement membrane with much of its strength.^{896,918} It consists of six genetically different chains (α_1 – α_6); it is produced by both keratinocytes and fibrocytes.⁹¹⁹ Type IV collagen is resistant to human skin collagenase but is a substrate for various neutral proteases derived from mast cells, macrophages, and granulocytes.⁸⁹⁶ Other antigenic components are laminin 1, nidogen, perlecan (formerly termed heparan sulfate proteoglycan), and chondroitin sulfate proteoglycan.^{900,904,919–921} Experiments using nidogen double-null mice embryos have shown that although nidogen is required for the formation of capillary basement membrane, it is not required for the formation of epidermal basement membrane.⁹²² It appears that the laminin composition of the various basement membranes determines whether nidogens are required for their assembly and stabilization.⁹²² It is believed that the structural elements laminin and type IV collagen form networks that are noncovalently interconnected by nidogen and perlecan. Nidogens appear to act as ‘stabilizers’ of molecular interactions, which promotes basement membrane remodeling, whereas perlecan forms links between laminin and type IV collagen networks that enhance mechanical properties of the basement membrane under steady-state conditions.⁹²³

Sublamina densa

The sublamina densa zone has a variety of components, but the major ones are the anchoring fibrils, which are the strongest mechanism in securing the epidermis to the dermis.⁸⁹⁷ The anchoring fibrils are curved structures with irregularly spaced crossbanding of their central portion.⁸⁹⁷ They fan out at either end, inserting into the lamina densa above and ‘anchoring plaques’ in the papillary dermis. These ‘anchoring plaques’ are composed of type IV collagen, laminin 332, and other components.⁹²⁴ Many fibrils form a sling around islands of type I and III collagen, and possibly oxytalan fibers, with both ends of the sling inserting into the lamina densa.^{897,924} The anchoring fibrils are composed of type VII collagen and laminin 332.^{924,925} Anchoring fibrils vary in their density in different regions of the body.⁹²⁰ The antigens AF-1 and AF-2 are associated with the sublamina densa zone. They may represent components of the anchoring fibrils additional to type VII collagen.⁹⁰⁰ The antibody LH 7:2 reacts with the central region of the N-terminal noncollagenous domain of type VII collagen.⁹²⁶ Antigens located in this region include the EBA (epidermolysis bullosa acquisita) antigen that is localized in part of the type VII collagen structure and the 285-kDa protein recognized in some cases of linear IgA bullous dermatosis. Commercially available antibodies to type VII collagen are now used.

Further reference to the basement membrane zone and the antigens within is made in the descriptions of the subepidermal blistering diseases that follow.

SUBEPIDERMAL BLISTERS WITH LITTLE INFLAMMATION

This heterogeneous group of vesiculobullous diseases includes variants of epidermolysis bullosa, porphyria cutanea tarda, the cell-poor type of bullous pemphigoid, burns, toxic epidermal necrolysis, suction blisters, the blisters that sometimes form over dermal scar or solar elastotic tissue, amyloid and IgM deposits, and some bullous drug reactions. An acute bullous eruption has been reported on the hand and forearm following extravasation of fluid being infused through an intravenous catheter. It is not mentioned further.⁹²⁷

EPIDERMOLYSIS BULLOSA

The term ‘epidermolysis bullosa’ is applied to a heterogeneous group of non-inflammatory disorders characterized by the development of blisters or erosions following minor trauma of the skin.^{920,928–932} Spontaneous blister formation may occur in some individuals. The clinical presentation may range from minimal involvement of the hands and feet to severe, life-threatening, generalized blistering with dystrophic changes and extracutaneous involvement.^{933–935} More than 600 different mutations have already been identified in the various genes involved in this condition.⁹³⁶

Epidermolysis bullosa is usually inherited as an autosomal dominant or recessive disorder, although an acquired form (see later) has also been recognized.⁹²⁹ The incidence of the hereditary forms is 1 : 50,000 births; the more severe recessive forms have an incidence of 1 : 200,000 to 1 : 500,000 births.⁹³³ In a study from Northern Ireland, 48 new cases of epidermolysis bullosa were recorded during a 23-year period (1962–1984). Of these 48 cases, 31 (65%) were of simplex type, 1 (2%) was of junctional type, 12 (25%) were of dystrophic type, and the remaining 4 (8%) were of the acquisita type.⁹³⁷ In another study from Scotland (population 5 million), 259 individuals with epidermolysis bullosa were identified. Of these, 149 had the simplex form, 108 the dystrophic form, and 2 the junctional form.⁹³⁸

These mechanobullous diseases are best classified into three subgroups on the basis of the level at which the skin separates.^{939,940} The three subgroups are as follows:

1. *Intraepidermal/epidermolytic* (epidermolysis bullosa simplex)
2. *Intralamina lucida/junctional* (junctional epidermolysis bullosa)
3. *Sublamina densa/dermolytic* (dystrophic epidermolysis bullosa).

A fourth (mixed) category, which includes Kindler’s syndrome, was added at the Third International Consensus Meeting, held in Vienna in 2007.⁹⁴¹ It was considered on page 76. It is a disorder of a new protein (called kindlin-1 or kindlerin, encoded by the gene *KIND1*) that binds actin microfilaments to the extracellular matrix via focal adhesion junctions at the dermal–epidermal junction. Thus, Kindler’s syndrome represents the first bullous disease to involve a primary abnormality of the actin cytoskeleton.⁹⁴² For convenience, all forms of epidermolysis bullosa are considered together because in the majority of cases the appearances on light microscopy are those of a cell-poor subepidermal blister; a few cases are intraepidermal. Routine histology is usually insufficient to allow classification of the various subtypes.⁹⁴³ Electron microscopy is the gold standard, but it is expensive, time-consuming, and not readily available.⁹⁴⁴ However, the use of immunohistochemical markers for laminin 1, type IV collagen, and keratin may assist considerably in the subclassification of an individual case.⁹⁴⁴ The use of frozen sections is superior to paraffin sections for some of these antibodies.⁹⁴⁵ In intraepidermal epidermolytic (simplex) forms, keratin is usually seen in the floor of the blister. Fluorescence mapping using specific monoclonal antibodies to the targeted protein is now the preferred method of diagnosis.^{941,946} It is unlikely that more than a few laboratories in any country will maintain stocks of these antibodies. The molecular defects, as currently known,⁹⁴⁷ are listed in Table 6.3. A proposal to add a subgroup of hemidesmosomal cases, to include the plectin-deficient variant of epidermolysis bullosa simplex with muscular dystrophy, has not been incorporated into the most recent classification.^{941,948,949} The intraepidermal/epidermolytic (simplex) group, which involves lysis of basal cells, is considered first. Before doing so, brief mention is made of the atypical nevi that may develop in all subsets of epidermolysis bullosa, particularly the recessively inherited variants.⁹⁵⁰ The dermoscopic pattern may mimic melanoma, but the absence of features such as irregular streaks, a blue-whitish veil, regression features, or black dots gives a distinctive dermoscopic pattern.⁹⁵⁰

Epidermolysis bullosa simplex

Epidermolysis bullosa simplex (EBS), one of the four major subgroups of epidermolysis bullosa (if Kindler's syndrome is accepted as the fourth category), is a mechanobullous disorder characterized by intraepidermal cleavage, usually through the basal layer of cells.^{928,951} There are several distinct clinical variants.⁹⁵² Most cases have a mild clinical expression with blisters that heal without scarring and an autosomal dominant inheritance.^{953,954} Rare cases with an autosomal recessive inheritance and a more severe clinical course, sometimes with associated neuromuscular disease (particularly muscular dystrophy), have been reported.^{955–957} Not all recessive forms have severe disease.^{958,959} A prenatal diagnosis was made in the past using fetal skin biopsy samples.^{910,960,961} Analysis of fetal DNA using chorionic villi or amniotic fluid cells is now the preferred technique.^{962–965} Keratinocyte cell lines have been established for EBS, providing a potential source for *in vitro* experiments using gene therapy.⁹⁶⁶

The molecular basis of most of the simplex subgroup resides in defects that disrupt the assembly, structure, and/or function of the keratin intermediate filament skeleton of the basal keratinocyte – the coexpressed peptides keratin 5 and 14.^{967–973} The keratin 5 (*KRT5*) gene maps to 12q13 and the keratin 14 (*KRT14*) gene to 17q12–q21. It appears that mutations in certain locations of the keratin genes (usually the ends of conserved α -helical rod domains) are more likely to produce the severe forms, such as the Dowling–Meara type (see later).⁹⁷⁴ Twelve subtypes of EBS are recognized in the latest classification (see Table 6.3), which is based on the Report of the Third International Consensus Meeting held in 2007.⁹⁴¹ Only the four major subtypes of EBS are considered in detail.

Other generalized type (includes Koebner variant)

The generalized (Koebner; OMIM 131900) clinical variant (now included in the ‘other generalized type’) is characterized by the development of serous blisters at birth or in early infancy.^{975,976} Blisters may involve the whole body, but they may be preferentially distributed on the hands and feet.⁹²⁸ Cases with oral involvement or with focal keratoderma of the palms and soles have been reported.⁹⁷⁷ The lesions tend to be worse in warmer weather, a feature present in several other variants. This variant results from a mutation in the keratin 5 (*KRT5*) or keratin 14 (*KRT14*) gene or both.⁹⁷⁸ Another term used for this category is ‘non-Dowling–Meara’.

Localized (Weber–Cockayne) type

The localized (Weber–Cockayne) form (OMIM 131800) is an autosomal dominant type in which friction-induced blisters are predominantly found on the hands and feet.^{928,952} It may also involve the flexures during hot weather and periods of disease activity.⁹⁷⁹ Enamel hypoplasia has been reported in a child with localized EBS.⁹⁸⁰ Onset is usually within the first 2 years of life, although it may be delayed into adolescence or beyond.⁹⁸¹ A kindred with autosomal recessive inheritance has been reported.⁹⁸² The disorder results from a mutation in the keratin 5 (*KRT5*) or keratin 14 (*KRT14*) gene or both.^{967,983,984} Most of the mutations have been situated in the L12 linker region of keratin 5, and in keratin 14.^{985,986}

Epidermolysis bullosa (Dowling–Meara)

Epidermolysis bullosa (Dowling–Meara), formerly called epidermolysis bullosa herpetiformis (OMIM 131760), is characterized by the development in the first few months of life of serous or hemorrhagic blisters on the trunk, face, and extremities.^{987,988} The blisters may have an arciform (herpetiform) arrangement,⁹⁸⁹ but this may be absent during periods of greatest disease activity.⁹⁷⁹ Inflammatory lesions may be present, and these sometimes heal with transitory milia or pigmentation. Mucosal lesions and nail involvement may occur, as may

keratoderma of the palms and soles.^{990–992} Some improvement occurs with age. Loose anagen hair syndrome has been reported in two patients,⁹⁹³ and atypical-appearing eruptive nevi have occurred (although a biopsy was not performed in this case).⁹⁹⁴ This variant has distinct ultrastructural features with clumping of tonofilaments.^{987,995–998} Although mutations may occur in either the keratin 5 (*KRT5*) or keratin 14 (*KRT14*) gene in this variant,^{999–1002} reports suggest that codon 125 of *KRT14* is frequently involved.^{991,1003–1005}

Epidermolysis bullosa simplex with muscular dystrophy (EBS-MD)

EBS-MD (OMIM 226670) is a rare autosomal recessive variant in which a defect in plectin has been found.¹⁰⁰⁶ Plectin is a 500-kDa cytoskeleton-associated protein that links the keratin intermediate filaments to the transmembrane proteins of the hemidesmosomes.^{1007–1009} Decayed teeth, urethral strictures, mild palmoplantar hyperkeratosis, respiratory complications,¹⁰¹⁰ alopecia,¹⁰¹¹ and ptosis and ophthalmoplegia¹⁰¹² may also occur. The muscular dystrophy may be of late onset.^{1013,1014} The majority of patients are products of consanguineous marriage and have homozygous plectin gene mutations.¹⁰¹¹ The gene for plectin, *PLEC1*, is located on chromosome 8q24. Plectin mutations are responsible for a variety of phenotypes: EBS-Ogna, EB-PA, and EB-MD.¹⁰¹⁵ A patient with EBS and mutations in the gene encoding plectin had both muscular dystrophy and pyloric atresia.¹⁰¹⁶ Abnormalities in plectin can also result from abnormalities in integrin β_4 .¹⁰¹⁷ Trans-splicing repair of the *PLEC1* gene has recently been achieved experimentally.¹⁰¹⁸

Other variants

Exceedingly rare variants include the autosomal dominant *Ogna type* (OMIM 131950) due to mutations in *PLEC1*, in which there are acral sanguineous blebs and a generalized bruising tendency,^{933,1019} the *Fischer and Gedde-Dahl type*,⁸²⁸ now called EBS-MP (OMIM 131960), in which the blistering tendency is accompanied by mottled pigmentation of the skin,^{828,1020–1022} the *migratory circinate form* (OMIM 609352), which may be followed by hyperpigmentation; and the *superficial type* (EBS superficialis), in which there is subcorneal cleavage mimicking the ‘scalded skin’ or peeling skin syndromes.¹⁰²³ There is an absence of plakophilin 1 in this condition, an abnormality that is seen in similar cases that are usually included with the ectodermal dysplasia–skin fragility syndrome (OMIM 604536)¹⁰²⁴ (see p. 317). The lethal acantholytic type (OMIM 609638) is an exceedingly rare autosomal recessive form.⁹⁴¹ It presents with oozing erosions rather than blisters.⁹⁴¹ Other findings have included alopecia universalis, anonychia, malformed ears, and cardiomyopathy.¹⁰²⁵ It is due to a mutation in the desmoplakin gene.¹⁰¹⁵ In one case, the mutation resulted in a lack of desmoplakin’s rod domain and C-terminus, and it correlated with ultrastructural absence of the desmosomal inner dense plaque.¹⁰²⁵ The genetic basis of the type with mottled pigmentation (EBS-MP), in five unrelated families, has been ascribed to a heterozygous point mutation in the nonhelical V1 domain of *KRT5*.^{1022,1026} Acral blistering begins in early childhood. Wart-like or punctate keratotic lesions also develop.¹⁰²⁷ Rarely, mutations in the *COL17A1* gene may result in split levels, suggesting EBS rather than junctional EB.¹⁰²⁸ An autosomal recessive variant (OMIM 601001) due to a mutation in the *KRT14* gene is yet another category of EBS.⁹⁷¹ Isolated reports claiming new clinical variants appear occasionally.^{957,1029–1031} The *Bart type*, in which there is congenital localized absence of the skin associated with trauma-induced blisters, is not a specific form of epidermolysis bullosa as sometimes claimed; it has been reported in association with the various subtypes of epidermolysis bullosa, including the simplex type.^{1032–1035} However, a study of descendants from the original case of Bart’s syndrome revealed it to be a subtype of dominantly inherited dystrophic (dermolytic) epidermolysis bullosa with the gene on chromosome 3p, at

or near the site of the gene encoding type VII collagen.¹⁰³⁶ The absence of skin may follow the lines of Blaschko.¹⁰³⁷

Histopathology

In EBS, the cleavage is so low in the epidermis that in routine paraffin sections the blister may appear to be a cell-poor subepidermal blister (Fig. 6.14).⁹⁵³ With thin plastic-embedded sections, fragments of basal keratinocytes may be observed in the blister base;⁹⁵³ the PAS-positive basement membrane is also found in that position. Immunofluorescence or immunoperoxidase techniques can also be used to confirm the level of the split. These methods will show that the bullous pemphigoid antigen, laminin, type IV collagen, and the LDA-1 antigen (a component of the lamina densa) are all present in the base of the bulla.^{944,1038,1039} Fragments of keratinocyte containing keratin can be detected in the base by the use of the monoclonal antibody MNF116.¹⁰⁴⁰ It also strongly stains the basal keratinocytes in the roof of the blister. Monoclonal antibodies to specific proteins such as keratin 5, keratin 14, and plectin are available in some laboratories.

In the localized (Weber–Cockayne) subtype, the level of the split is usually in the mid or upper epidermis (Fig. 6.15), although induced blisters develop in the basal layer.^{1041,1042} In one case that clinically resembled this subtype, suprabasal acantholysis resembling Hailey–Hailey disease was present.¹⁰⁴³ In epidermolysis bullosa (Dowling–Meara), a number of eosinophils may be found in the underlying papillary dermis.^{1044,1045} They are not specific for this variant and may be found in other subtypes. Intracytoplasmic homogenizations and inclusions (dyskeratosis) are often present in individual keratinocytes.¹⁰⁴⁶ Extensive acantholysis was found in a recent case of Dowling–Meara epidermolysis bullosa – a finding that raised differential possibilities of neonatal pemphigus or lethal acantholytic epidermolysis bullosa.¹⁰⁴⁷ In EBS-MD, the blister formation always occurs just above the hemidesmosome. The expression of plectin is absent or markedly reduced.¹⁰¹¹ In the lethal acantholytic type, there is suprabasal clefting with acantholysis.¹⁰¹⁵ A rare variant with subcorneal splitting has been reported (discussed previously);¹⁰²³ a variant with enlarged dyskeratotic basal cells that have eosinophilic clumps in the cytoplasm and show some atypical mitoses is also rare.¹⁰⁴⁸

Transient intraepidermal blisters with the appearances of EBS can be seen at the donor sites of skin grafts taken for use in patients who have had toxic epidermal necrolysis.¹⁰⁴⁹

Electron microscopy

There is some perinuclear edema and subnuclear cytolysis of the basal cells,⁹⁷⁷ but organelles are usually intact. In epidermolysis bullosa (Dowling–Meara), the cytolysis is preceded by aggregation and clumping of the tonofilaments that are attached to the hemidesmosomes at the dermoepidermal junction.^{987,990,1050} The tonofilament clumps may be round or ‘whisk type’.⁹⁸⁹ The basement membrane zone is intact in all variants of EBS.

Junctional epidermolysis bullosa

Junctional (‘lamina lucidolytic’) epidermolysis bullosa (JEB) comprises an extremely rare group of mechanobullous diseases characterized by autosomal recessive inheritance, lesions that heal without scarring (although in time atrophy may develop), and separation between the basal cells and the lamina lucida due to reduced numbers/function of the hemidesmosomes.^{939,1051,1052} Eight subtypes of JEB are recognized in the latest classification of epidermolysis bullosa.^{941,949} It includes for the first time the LOC (*laryngo-onycho-cutaneous*) syndrome, also known as Shabbir’s syndrome (OMIM 245660). It occurs in children of Punjabi origin.¹⁰⁵³

- Herlitz type (JEB-H)
- Non-Herlitz type (JEB-nH)

Figure 6.14 Epidermolysis bullosa simplex. (A) Cleavage in the base of the epidermis. (B) Fragments of the basal keratinocytes are present in the floor of the blister. There is no dermal inflammation. (C) There is vacuolar change within keratinocytes, prior to cleavage. (H&E)

Figure 6.15 (A) Epidermolysis bullosa simplex (localized, Weber-Cockayne type). (B) The split is in the mid epidermis. (H&E)

- Non-Herlitz-generalized
- Non-Herlitz-localized
- With pyloric atresia (JEB-PA)
- Inversa (JEB-I)
- Late onset (JEB-lo)
- LOC syndrome.

The non-Herlitz group includes cases previously reported as generalized atrophic benign epidermolysis bullosa – GABEB, a designation that may be difficult to dislodge from the literature.

Six antigenic defects have been detected in the basement membrane zone in cases of JEB.^{1054–1060} The six genes and the associated proteins encoded by them are as follows:

- *LAMA3* – α_3 subunit of laminin 5 (now known as laminin 332)
- *LAMB3* – β_3 subunit of laminin 5
- *LAMC2* – γ_2 subunit of laminin 5
- *COL17A1* – type XVII collagen (BP180, BPAg2)
- *ITGA6* – α_6 integrin
- *ITGB4* – β_4 integrin.

Mutations in genes encoding laminin 5 have been demonstrated in cases of Herlitz (JEB-H) and non-Herlitz (JEB-nH) type.¹⁰⁶¹ *LAMB3*

mutations account for more than 70% of the mutations found in JEB.¹⁰¹⁵ Recently, recombinant β_3 chains were inserted into laminin 5 deficient in these chains, in cultured keratinocytes *in vitro*.¹⁰⁶² Other patients with JEB-nH may have mutations in the *COL17A1* gene located at 10q24.3. Mutations in either of the genes encoding $\alpha_6\beta_4$ integrin underlie JEB-PA. There is a high incidence of consanguinity in this variant of EB.¹⁰⁶³ Uncein, a protein on the anchoring filaments and recognized in the past by the monoclonal antibody 19-DEJ-1, is absent in nearly all patients with JEB and 25% of those with the recessive dystrophic (dermolytic) form.^{909,1064,1065} Interestingly, two acquired subepidermal blistering diseases (cell poor), one with autoantibodies to uncein and the other with antibodies to the β subunit of laminin 5, have been reported.¹⁰⁶⁶ The term 'acquired junctional epidermolysis bullosa' is appropriate for these cases.⁹¹⁵ The various molecular abnormalities in JEB appear to affect certain critical intracellular functions of hemidesmosomes, such as the normal connections with keratin intermediate filaments.¹⁰⁶⁷

Reduced adhesion of keratinocytes in culture has also been reported;¹⁰⁶⁸ this appears to result from defective hemidesmosome synthesis.¹⁰⁶⁹ Absence of the α_3 polypeptide chain of laminin 5, which occurs in the LOC syndrome, seems to cause excessive granulation tissue production at wound sites. This is also a problem in other types of JEB.¹⁰⁷⁰

Eight variants are included in the latest classification.⁹⁴⁹

Junctional epidermolysis bullosa – Herlitz type (JEB-H)

JEB-H (OMIM 226700), known in the past as epidermolysis bullosa atrophicans gravis (epidermolysis bullosa letalis), has severe generalized involvement with acral accentuation.^{1071–1073} Erosions and bullae are present at birth. Large nonhealing areas of granulation tissue develop on the nape of the neck and in the perioral region. Most affected individuals die in early infancy, but a few have survived for longer periods.⁹²⁸ Among patients with JEB-H in the Dutch Epidermolysis Bullosa Registry, the average age at death was 5.8 months, and natural causes of death were failure to thrive, respiratory failure, pneumonia, dehydration, anemia, and sepsis.¹⁰⁷⁴ Clinical associations have included anemia, oral lesions, blepharitis, anonychia, and epithelial separation in various internal organs.^{1075–1077} Defects in all three polypeptide chains (α_3 , β_3 , and γ_2) of laminin 5 have been recorded in different families.^{911,1078–1080} Mutations in the *LAMB3* gene on chromosome 1q32.2, particularly the mutation R635X, are found more often than mutations in the other two genes for laminin 5.^{1081–1085} Approximately 150 distinct mutations have been identified in the laminin 5 genes.^{1086,1087} Mutations can be detected by DNA-based prenatal testing in families at risk for JEB. In one report, testing revealed one affected and one normal twin. Selective termination of the affected fetus was carried out, and pregnancy with the unaffected fetus was continued.¹⁰⁸⁸ Preimplantation genetic haplotyping, in the course of an *in vitro* fertilization procedure, has now been developed and applied to the diagnosis of JEB-H.¹⁰⁸⁹

Junctional epidermolysis bullosa – non-Herlitz (JEB-nH)

JEB-nH (OMIM 226650), known in the past as epidermolysis bullosa atrophicans mitis (generalized atrophic benign epidermolysis bullosa – GABEB), is now used for all cases of JEB of non-Herlitz type. As such, it includes generalized and localized forms, JEB with pyloric atresia, JEB inversa, late-onset JEB, and the LOC syndrome.⁹⁴¹ The *generalized* form is characterized by lesions that heal with atrophy and mild scarring, but there are usually no milia or contractures.^{1090–1096} There may be some improvement with age. Alopecia and absence of pubic and axillary hair are other clinical features.⁹³³ Multiple squamous cell carcinomas of the skin may develop in adult life,^{1097,1098} and there appears to be an increased risk of developing lower extremity squamous cell carcinomas among adult patients with JEB-nH.¹⁰⁹⁹ Several different molecular defects have been reported in this subtype. Most

of the mutations involve the *COL17A1* gene, responsible for the formation of the type XVII collagen.^{1100–1104} Among patients in this subgroup, the presence of even minor amounts of collagen XVII is associated with relatively mild cutaneous involvement.¹¹⁰⁵ A minority of the mutations involve the *LAMB3* gene encoding the β_3 polypeptide of laminin 5,^{1106,1107} the *LAMC2* gene encoding the γ_2 chain,¹¹⁰⁸ and *LAMA3* encoding the α_3 chain.¹⁰¹⁵ A patient with defects in both *COL17A1* and *LAMB3* genes (digenic) has been reported.¹¹⁰⁹ In a few cases, a deficiency of LAD-1, a portion of the extracellular domain of BP180, has been present.^{1110–1112} A mosaic expression of BP180, LAD-1, and uncein has been reported in one patient.¹¹¹³ Some patients with mutations in *COL17A1* may have a bullous pemphigoid-like eruption with pruritus and eosinophilia. Response to oral corticosteroids has been reported in one such case.¹¹¹⁴

The *localized* variant, formerly known as epidermolysis bullosa atrophicans localisata, has its onset at birth or early in neonatal life. Lesions are usually restricted to the soles and pretibial area.^{933,1115} In patients with *COL17A1* mutations, a localized phenotype can be differentiated from the generalized phenotype by IF antigen mapping.¹¹¹⁶ The localized variant can be treated by skin grafting.¹¹¹⁷

The variant of JEB with pyloric atresia (JEB-PA; OMIM 226730) may also present with aplasia cutis congenita and/or ureterovesical junction obstruction.^{1051,1118–1127} More than 60 patients with this condition have been reported worldwide.¹⁰¹⁵ The molecular defect involves $\alpha_6\beta_4$ integrin, a heterodimeric protein that has been isolated from most epithelial linings. Mutations in either the α_6 (*ITGA6*) or β_4 (*ITGB4*) gene have been associated with JEB-PA.^{1057,1128} Mutations in *ITGB4* are more common, accounting for 85% of all cases of JEB-PA.¹⁰¹⁵ There is rapid intracellular degradation of the mutated β_4 chains.¹¹²⁹ Approximately 10% of cases involve the plectin (*PLEC1*) gene. Rarely, pyloric atresia occurs in the setting of epidermolysis bullosa simplex.^{1130,1131}

JEB inversa, formerly known as epidermolysis bullosa atrophicans inversa, has intertriginous lesions.^{941,1132} There are deficiencies in laminin 5. Improvement occurs with age. *Epidermolysis bullosa junctionalis progressiva* is a rare form that presents with nail dystrophy followed some years later by acral blisters.^{1133,1134} This may be the form now known as JEB, *late onset*, but no references are given to this entity in the new classification that allows for confirmation.⁹⁴¹ *Cicatricial junctional epidermolysis bullosa* clinically resembles the dystrophic forms, with lesions present at birth that heal with scarring.^{680,1135} Contractures and scarring of the anterior nares may develop, as may oral and laryngeal lesions.¹¹³⁵ This category is not mentioned in the new classification. Presumably it forms part of the non-Herlitz category. Brief mention has already been made of the LOC syndrome.

Histopathology

The junctional forms appear as subepidermal, cell-poor blisters with the PAS-positive basement membrane in the floor (Fig. 6.16). Laminin and type IV collagen can also be demonstrated in the base of the blister; the bullous pemphigoid antigen can be detected in the roof.^{944,1039,1090} If atrophy develops, there is thinning of the epidermis and flattening of the rete ridges. Dermal fibrosis is present in the cicatricial variant.

Electron microscopy

The various junctional forms cannot be distinguished ultrastructurally. They all show separation through the lamina lucida with variable hypoplasia of the hemidesmosomes.^{1136,1137} In JEB-H, sub-basal dense plates were also hypoplastic or absent.¹¹³⁸ Disruption of the basement membrane and an increase in dermal fibroblasts are present in the cicatricial variant.¹¹³⁵ Amorphous deposits have been reported in the lamina lucida in epidermolysis bullosa progressiva, but this finding has not been confirmed subsequently.¹¹³³

Figure 6.16 Junctional epidermolysis bullosa. There is a cell-poor subepidermal blister. The biopsy was obtained from a patient with Herlitz-type disease.

Dystrophic epidermolysis bullosa

The dystrophic forms of epidermolysis bullosa (DEB) present with trauma-induced blistering that is followed by the formation of scars and milia.^{1139–1141} Although the old classification recognized 3 major subtypes, traditionally 6 had been reported, 3 of which were inherited in an autosomal dominant manner. The remainder were recessive in type, and in these cases the lesions tended to be more severe. The new classification, published in 2008 and based on the Third International Consensus Meeting held in Vienna, Austria, in 2007, recognizes 13 subtypes of DEB, of which 6 are inherited as autosomal dominant traits (DDEB) and 7 as autosomal recessive conditions (RDEB).⁹⁴¹ All subtypes are due to mutations in *COL7A1*. Most patients with DEB have relatively mild, dominantly inherited disease.¹¹⁴²

Analysis of fetal DNA obtained from chorionic sampling or amniotic fluid cells allows the diagnosis to be made accurately and in the first trimester.^{1143–1145} Previously, the diagnosis was made by fetal skin biopsy.¹¹⁴⁶ The challenges of gene therapy are now being addressed.^{1147,1148}

Other clinical features that may be present in DEB include nail dystrophy,¹¹⁴⁹ and oral¹¹¹⁸ and gastrointestinal lesions,¹¹⁵⁰ particularly esophageal webs and strictures.¹¹⁵¹ A variant of autosomal dominant DEB has nail changes as its only manifestation.⁹⁴¹ One case demonstrated a slate gray appearance of dermal scars, resulting from frequent application of silver sulfadiazine cream; silver granules were microscopically identifiable with in the upper dermis.¹¹⁵² Congenital localized absence of the skin,^{1033,1153,1154} anemia, growth retardation, and poor nutrition may also be present.^{1155–1157} Squamous cell carcinomas (SCC) of the skin are a not uncommon complication,^{1147,1158–1163} which may be linked to the persistent growth-activated immunophenotype of epidermal keratinocytes that has been found in this disease (see later).¹¹⁶⁴ Mutant p53 protein is found in only one-fourth of the tumors, possibly a reflection of their well-differentiated nature.¹¹⁶⁵ Recent studies indicate that transforming growth factor- β 1 signaling plays an important role in the development and progression of SCC in these patients.¹¹⁶⁶

A trial of isotretinoin has been commenced in an attempt to reduce the risk of SCC developing in patients with the recessive variant.¹¹⁶⁷ Atypical melanocytic lesions have been reported.^{950,1168} Systemic amyloidosis, glomerulonephritis, Marfan's syndrome, cardiomyopathy,^{1169,1170} and herpetic infection are other rare associations.^{1171–1176} A case has been reported of coexistent DEB and X-linked ichthyosis;

partial deletion of the *STS* gene (the gene encoding steroid sulfatase) and a recessive point mutation in *COL7A1* were both demonstrated.¹¹⁷⁷ The development of an astrocytoma in one patient with the severe recessive form may have been fortuitous.¹¹⁷⁸

The dermolytic (dystrophic) variants are all characterized by the development of a split below the lamina densa in the region of the anchoring fibrils. These fibrils are usually absent or severely diminished in the severe recessive form and reduced in number in many of the other types.^{1179,1180} In cases with normal numbers of anchoring fibrils, it is assumed that they may be qualitatively changed.¹¹⁸¹ Abnormal collagenase activity has been demonstrated in some of the recessive forms, but it appears to play a minor pathogenetic role.^{1182–1184} Nevertheless, it is interesting that drugs which inhibit collagenase and proteases have a favorable therapeutic effect on the course of the disease.^{933,1185,1186} Matrix metalloproteinase 7 (MMP-7) appears to play a role in the epidermal detachment that occurs in recessive DEB.¹¹⁸⁷

Type VII collagen, the major – if not the exclusive – component of the anchoring fibrils, is markedly reduced or absent in all but rare cases of the recessive form; it is also reduced or 'defective' in many of the dominant forms of dermolytic (dystrophic) epidermolysis bullosa.^{1181,1188–1193} Rare cases of the recessive variants with normal type VII collagen (e.g., the inversa form) may represent mutations affecting interactions of the anchoring fibrils with other components of the basement membrane zone or in the structural assembly of the fibrils.^{1194,1195} Elastic microfibrils might contribute to dermal–epidermal adherence in areas with intact skin but an absence of anchoring fibrils.¹¹⁹⁶

The synthesis of type VII collagen is under the control of the gene *COL7A1*, on chromosomal locus 3p21.¹¹⁹⁷ There is a strong genetic linkage between this gene and both dominant and recessive forms of dermolytic (dystrophic) epidermolysis bullosa.^{1197–1199} A glycine-to-arginine substitution in the triple-helical domain of type VII collagen, a mutation designated as G2043R, is the classic mutation in the dominant forms.^{1200–1202} In some but not all cases, the same glycine substitution mutations are found in both dominant and recessive dystrophic disease.¹²⁰³ More than 500 different mutations have been reported.^{1204–1210} Most *COL7A1* mutations are unique to individual families, and therefore it is usually necessary to screen all 118 exons of the gene to determine the molecular pathology in a patient with DEB.^{1211–1217} Several recurrent mutations have been reported.^{1218,1219} The less severe forms of recessive DEB have been found to be heterozygous for the usual defect in *COL7A1* but with a further different mutation in the other allele.^{1220–1222} DNA sequencing may be useful in determining the inherited basis of some sporadic cases of DEB.¹²²³

Studies with cultured keratinocytes have produced conflicting results, with reports of reduced production of type VII collagen¹²²⁴ but sometimes with normal amounts of collagen VII mRNA,¹²²⁵ normal production,¹¹⁹³ and even intracellular accumulation.¹²²⁶

Revertant mosaicism has been described in a patient with recessive DEB, resulting from a second-site mutation in *COL7A1*; this manifested as a patch of clinically normal skin on the patient's forearm. The authors suggest that revertant keratinocytes might be exploited as a potential therapy in these individuals.¹²²⁷ The various clinical types of dermolytic epidermolysis bullosa are discussed next. Variants with both an autosomal dominant and recessive mode of inheritance are discussed together.

Dominant dystrophic epidermolysis bullosa, generalized variant

In this dominant form (OMIM 131750), blisters commence at birth or in early childhood, but they are usually not debilitating.^{941,1228} There is a predilection for acral regions, particularly the extensor surfaces.⁹³⁹ The scars that develop may be hypertrophic.⁹³³ This generalized variant includes both the old Cockayne–Touraine and the Pasini types, which are allelic, and differences in the clinical phenotype may reflect the precise position of the glycine substitution along the type VII collagen molecule.¹²⁰⁰ Several different mutations in *COL7A1* have been

reported.^{1229–1231} The old Pasini category included cases that developed pale papules (albopapuloid lesions) on the trunk at puberty.¹²³²

Dystrophic epidermolysis bullosa, acral variant

This variant, which has both an autosomal dominant and an autosomal recessive form, is characterized by onset in early infancy of blistering lesions on the hands and feet. Milia and scarring eventuate. Nails may be dystrophic or absent.⁹⁴¹

Dystrophic epidermolysis bullosa, pretibial variant

Pretibial epidermolysis bullosa (OMIM 131850) is a rare dominant or recessive form associated with pretibial blisters that may be present at birth or develop in childhood or adolescence.^{1233–1235} The hands and feet may also be involved.⁹⁴¹ Albopapuloid lesions are occasionally present.^{928,1236} The inflammatory nature of some lesions may mask the diagnosis for some time.¹²³⁷ The anchoring fibrils are sparse and rudimentary in both lesional and nonpredilected normal skin.¹²³⁶ Mutations in the collagen type VII gene *COL7A1* have been found.^{1238,1239}

Dystrophic epidermolysis bullosa, pruriginosa

Both an autosomal dominant and a recessive form of EB pruriginosa (OMIM 604129) exist.^{1240–1244} Sporadic cases also occur. It is characterized by the presence of prurigo nodularis-like lesions in a localized or more generalized distribution. Its onset is usually in childhood, although a recent report describes onset of the disorder in a 71-year-old man.¹²⁴⁵ Blisters, milia, and hypertrophic scarring may also be present.^{941,1246} The scarring is most evident on the limbs, particularly the shins.^{1247,1248} Factors other than *COL7A1* mutations may be responsible for this distinctive phenotype,¹²⁴² although the mutations responsible are usually in glycine residues within Gly-X-Y repeats.¹²⁴⁹ Filaggrin (*FLG*) mutations do not contribute to this phenotype.¹²⁵⁰ Topical tacrolimus has been used successfully to treat this form of the disease,¹²⁵¹ so, too, has thalidomide.¹²⁴⁷

Recessive dystrophic epidermolysis bullosa, severe generalized form

This variant of EB, formerly known as the Hallopeau–Siemens variant (OMIM 226600), is highly debilitating and characterized by large flaccid bullae on any part of the skin from birth.¹²³² The erosions that form after rupture of the blisters are slow to heal.¹²⁵² There is a range of severity, with a shortened life span in the severe (gravis) forms.^{933,939,1253} The scarring often leads to digital fusion and so-called ‘mitten’ deformities.^{1254,1255} The oral, esophageal, anal, and vaginal mucosae are frequently involved with the development of fibrous strictures.¹²⁵⁶ Sparse hair, dystrophic teeth,¹²⁵⁷ keratitis,¹²⁵⁸ and growth retardation are common features.⁹³⁹ Bone mineralization is diminished in these patients, which may put them at risk for fragility fractures.¹²⁵⁹ This category of EB has the greatest risk of developing cutaneous SCC. The cumulative risk is 76.5% by the age of 60 years compared with a lifetime risk of cutaneous SCC in the non-EB population of the United States of 9–14% among men and 4–9% among women.^{1160,1260} Atypical melanocytic lesions also develop in this variant of EB.¹²⁶¹ A variant with progressive, symmetrical, centripetal involvement exists.^{939,1262} Recessive dystrophic epidermolysis bullosa centripetalis is a separate category in the new classification system, but little else is known about it.⁹⁴¹ Compound heterozygosity may lead to a milder phenotype in RDEB,¹²⁶³ although moderately severe disease has been reported in some patients with this abnormality.¹²⁶⁴ Deafness was also present in one compound heterozygote.¹²⁶⁵ Sclerodermoid lesions have been reported in one patient with this disorder.¹²⁶⁶ Heterozygotes appear to have diminished numbers of anchoring fibrils.¹²⁶⁷

Graft skin has been used successfully to treat skin defects in this condition, leading to improved quality of life.¹²⁶⁸ Autologous cultured

keratinocytes have also been used.¹²⁶⁹ Recently, allogeneic fibroblasts have been injected into the dermis of lesional skin with improvement in skin fragility.¹²⁷⁰ Other potentially promising therapeutic approaches include intradermal infusion of mesenchymal stromal cells,¹²⁷¹ bone marrow stem cell therapy,¹²⁷² and fibroblast-based cell therapy.¹²⁷³ The mechanism for the latter may be the induction of *COL7A1* expression in keratinocytes and fibroblasts by heparin-binding EGF-like growth factor.¹²⁷⁴

Recessive dystrophic epidermolysis bullosa, generalized other

This category (OMIM 132200) in the new classification is composed of cases previously categorized as ‘non-Hallopeau–Siemens’.⁹⁴¹ Lesions are generalized and present at birth. Lesions are less severe than in the Hallopeau–Siemens type. Like other variants of EB, it involves mutations in *COL7A1*.

Dystrophic epidermolysis bullosa inversa

In recessive, dystrophic epidermolysis bullosa inversa, blisters develop on the trunk and extremities in early infancy. Thereafter, there is a predilection for the involvement of the skin of the axillae, neck, and lower part of the trunk with sparing of the extremities.^{1275,1276} Milia are often absent. Mucosal involvement is common, and the tongue may be bound to the floor of the mouth.¹²⁷⁵ Ultrastructural analysis reveals absent or rudimentary anchoring fibrils, although type VII collagen is present on immunofluorescence.¹²⁷⁷ This implies a defect in the supramolecular aggregation of collagen VII into anchoring fibrils.^{1276–1278} The absence of the anchoring fibril-associated protein GDA-J/F3 has been reported.¹²⁷⁹ Recently, specific recessive arginine and glycine substitutions in the triple helix domain of type VII collagen have been identified in this form of recessive DEB.¹²⁸⁰

Bullous dermolysis of the newborn

Bullous dermolysis of the newborn (OMIM 131705) is a rare autosomal dominant or recessive variant, which is characterized by a self-limited course and the presence of abundant type VII collagen within the cytoplasm of basilar and, to a lesser extent, suprabasilar keratinocytes.^{1281–1285} Because some cases persist, the word ‘transient’ was deleted from the title in the recent classification.⁹⁴¹ Lesions are present at birth or develop in early infancy. There may be blisters and also milia followed by atrophic scarring. Milia are sometimes the dominant feature.¹²⁸⁶ Skeletal abnormalities such as pseudosyndactyly are rare.¹²⁸⁷ There is only patchy basement membrane zone staining for type VII collagen, but this reverts to normal with clinical improvement. This condition may result from delay in the transport and integration of type VII collagen or excessive phagocytosis by basal keratinocytes.¹²⁸⁸ In addition, there are mutations in the *COL7A1* gene.^{1289–1292} Occasionally, small amounts of similar cytoplasmic type VII collagen can be seen in other types of dermolytic (dystrophic) epidermolysis bullosa, particularly during wound healing in severe forms of the disease.¹²⁹³ Bullous dermolysis of the newborn and DEB pruriginosa have been found within the same family.¹²⁹⁴

Histopathology

Routine light microscopy is of little value in the diagnosis of the dystrophic (dermolytic) forms of epidermolysis bullosa.¹⁰⁵⁶ There is a cell-poor, subepidermal blister. Uncommonly, there are sparse eosinophils in the dermis;¹⁰⁴⁵ they were numerous in one case.¹²⁹⁵ Superficial dermal scarring and milia are often present (Fig. 6.17). Amyloid deposits were found beneath the blister base in a case of pretibial DEB; this particular patient may have had coexistent lichen amyloidosis.¹²⁹⁶ The PAS-positive basement membrane, the bullous pemphigoid antigen, laminin, and types IV and V collagen are all found in the roof of the blister.^{944,1038,1297} Staining is weak or absent with antibodies to

Figure 6.17 Recessive dystrophic epidermolysis bullosa. There is an infiltrate-poor subepidermal bulla. Scarring is present in the underlying dermis.

KF-1, AF-1, and AF-2, which are all components of the anchoring fibrils.^{933,1039,1056} If a monoclonal antibody to type VII collagen is used (LH 7:2 or commercial preparations), staining will occur in the genetically dominant dermolytic forms but only weakly or not at all in the recessive forms.^{1139,1190,1298} Studies have shown that LH 7:2 reacts with the central region of the N-terminal noncollagenous domain of type VII collagen.⁹²⁶

Electron microscopy

The anchoring fibrils are usually totally absent in the generalized recessive form and diminished in number in both the localized recessive and the dominant variants.^{939,1180} The split occurs beneath the lamina densa.¹⁰⁵⁰ Perinuclear stellate inclusions are seen in basilar keratinocytes in transient bullous dermolysis of the newborn.¹²⁸⁸ They represent cytoplasmic type VII collagen.

Epidermolysis bullosa acquisita

Epidermolysis bullosa acquisita (dermolytic pemphigoid, EBA) is a rare, nonhereditary, subepidermal bullous disorder with heterogeneous clinical features.¹²⁹⁹⁻¹³⁰² Typically, there are non-inflammatory bullae that develop in areas subjected to minor trauma, such as the extensor surface of the limbs.¹³⁰³ A localized variant has been reported.¹³⁰⁴ One case began with lesions mimicking eyelid dermatitis.¹³⁰⁵ Rare cases have been precipitated by prolonged sun exposure.¹³⁰⁶ The lesions eventually heal, leaving atrophic scars and milia. In up to 50% of cases, the initial presentation is with widespread inflammatory bullae, which are not precipitated by trauma and which heal without scarring.^{1299,1307,1308} Some such cases, if not all, eventually evolve into the non-inflammatory (mechanobullous), scarring type.¹²⁹⁹ At times, the clinical presentation may mimic bullous pemphigoid,^{1309,1310} localized cicatricial pemphigoid,^{1304,1311,1312} mucous membrane pemphigoid,¹³¹³ or linear IgA bullous dermatosis.¹³¹⁴ The confocal laser scanning microscope has been used with some success in distinguishing bullous pemphigoid from EBA.^{1304,1315}

Involvement of the mucous membranes occurs in 30–50% of cases.¹³¹⁶ This usually takes the form of oral erosions and blisters, but ocular involvement can also occur.¹³¹⁷ A variant with ocular involvement, sometimes severe, and IgA autoantibodies has been reported.^{1314,1318,1319} IgA-EBA is clinically indistinguishable from the inflammatory type of IgG-EBA and from the classic 'lamina-lucida type' of linear IgA dermatosis. Only a minority of patients with IgA-EBA show milia or scarring

or have therapy-resistant ocular disease.¹³²⁰ Vesicular cystitis,¹³²¹ esophageal webs,¹³²² and scarring alopecia¹³²³ are rarely present.¹³²⁴

Onset of the disease is usually in mid-adult life, although some cases have been reported in children.¹³²⁵⁻¹³³⁸ A rare case has been described of vertical transmission of antibody from a mother with EBA to her infant, resulting in transient blistering in the newborn.¹³³⁹ Its course is usually chronic, and there is great variability in severity and evolution.^{1299,1340,1341}

EBA has been associated with various systemic diseases, particularly those with a presumed immune pathogenesis.^{1299,1303} They include SLE,^{1342,1343} scleroderma,¹³⁴⁴ rheumatoid arthritis, inflammatory bowel disease^{1323,1345} (particularly Crohn's disease),¹³⁴⁶ anti-p200 pemphigoid,¹³⁴⁷ hepatitis C,¹³⁴⁸ chronic thyroiditis, HIV infection,¹³⁴⁹ psoriasis,¹³⁵⁰ amyloidosis,¹³⁵¹ multiple myeloma,¹³⁵² mixed cryoglobulinemia,¹³⁵³ acquired hemophilia,¹³⁵⁴ and the multiple endocrinopathy syndrome.¹³⁵⁵ Its association with a benign schwannoma was probably coincidental.¹³⁵⁶ Its onset has also been triggered by pregnancy,¹³⁵⁷ antibiotics,¹³⁵⁸ and penicillamine.¹³⁵⁹

Earlier views¹³⁶⁰ that this condition was not a distinct entity but a variant of mucous membrane pemphigoid were put to rest by the discovery of the EBA antigen.¹³⁶¹⁻¹³⁶⁴ This antigen, with a molecular weight of 290 kDa, is type VII collagen,¹³⁶⁵⁻¹³⁶⁷ a major component of the anchoring fibrils.¹³⁶⁸ It appears to be synthesized by both fibroblasts and keratinocytes.¹³⁶³ The initiating event in this dermatosis is probably the formation and binding of antibody to the C-terminal region of type VII collagen.^{1365,1368} Multiple epitopes exist on the N-terminal noncollagenous domain of type VII collagen, capable of binding the autoantibodies in this disease.¹³⁶⁹ In one study, 20 of the 28 sera tested reacted with the NC1 domain located in the lamina densa, whereas 8 sera reacted with the smaller C-terminal NC2 domain in the dermis, below the lamina densa.¹³⁷⁰ In several cases reported subsequently, the patients' antibodies reacted to all three structural domains of type VII collagen – NC1, NC2, and the triple-helical domain.^{1371,1372} In some children, autoantibodies target only the triple-helical domain. Sequence analysis of the NC1 domain reveals multiple submodules with homology to adhesive proteins such as fibronectin and cartilage matrix protein (CMP). The CMP domain on type VII collagen is the first antigen epitope on type VII collagen demonstrated to be a pathogenic target for EBA autoantibodies.¹³⁷³

ELISA using recombinant NC1 or NC1 and NC2 domains has been shown to be a sensitive and specific means of diagnosing and following antibody titers of EBA patients;¹³⁷⁴ similarly useful assays using ELISA and immunofluorescence methods directed toward NC1 in human HEK293 cells have also been developed.¹³⁷⁵ Passive transfer of type VII autoantibodies from a patient with severe EBA produced comparable changes when injected subcutaneously into neonatal mice.¹³⁷⁶ An infant with multiple tense blisters and autoantibodies to both the EBA antigen and BP180 has been reported.¹³⁷⁷ A patient with inflammatory EBA and coexistent IgA antibodies to plectin has been reported.¹³⁷⁸ In a further patient, there were IgG autoantibodies to type VII collagen and an exclusive IgG3 reactivity to the laminin α_3 chain.¹³⁷⁹

Antibodies to type VII collagen are also found in many cases of bullous SLE.^{1301,1380} Patients who develop apparent EBA in association with systemic lupus erythematosus (SLE) have been regarded as a subset of the bullous eruption of SLE.^{1381,1382}

EBA is often a difficult lesion to treat. A combination of corticosteroids and immunosuppressants such as azathioprine, cyclosporine, and colchicine is often given. Intravenous immunoglobulins have also been used successfully in the treatment of EBA.¹³⁸³⁻¹³⁸⁸ Prednisone combined with dapsone is used less often, but dapsone is the most effective therapy for IgA-mediated EBA.¹³²⁰ Mycophenolate mofetil has been tried as a corticosteroid-sparing agent.¹³⁸⁹ The anti-CD20 monoclonal rituximab has been tried in cases resistant to other therapy.^{1390,1391} Rituximab has also been combined with immunoadsorption.¹³⁹²

Figure 6.18 Epidermolysis bullosa acquisita (EBA). This is a non-inflammatory lesion. (H&E)

Histopathology¹²⁹⁹

There is a subepidermal bulla with fibrin and only a few inflammatory cells in the lumen.¹³⁹³ The roof of the blister is usually intact, and there may be a few dermal fragments attached to the epidermis.¹³⁹⁴ In non-inflammatory lesions (Fig. 6.18), there is a sparse lymphocytic infiltrate around the vessels of the superficial vascular plexus, whereas in inflammatory lesions there is a heavy upper dermal inflammatory infiltrate in which neutrophils predominate.¹³⁰⁷ The neutrophils often form papillary microabscesses (Fig. 6.19). Some eosinophils may also be present. The histological heterogeneity presumably results from the heterogeneity of the immune complexes that are deposited, some having greater ability than others to generate complement-derived chemotaxis. In older lesions, there will be some dermal scarring and also milia.

With the PAS stain, the basement membrane is split, and most of the PAS-positive material is attached to the blister roof.¹³⁹³ Laminin and type IV collagen can be identified by immunoperoxidase techniques in the roof of the blister.^{1395,1396} This technique is helpful if facilities are not available for immunoelectron microscopy or split-skin immunofluorescence (see later).

Figure 6.19 Epidermolysis bullosa acquisita (EBA). Inflammatory lesions may show papillary neutrophilic microabscesses.

Direct IF shows linear deposition of immunoglobulins, particularly IgG, and of complement (including the complement components C3b and C5)¹³⁹⁷ along the basement membrane zone in nearly all lesions;^{1323,1351} cases reported without immunoreactants may form a distinct subgroup.^{1394,1398,1399} A useful clue to the presence of antibodies targeting type VII collagen (EBA and bullous lupus erythematosus) is the presence of a u-serrated pattern of linear IgG deposition,¹⁴⁰⁰ which is considered by some to be the 'gold standard' for diagnosing EBA¹⁴⁰¹ and provides a helpful distinction from the n-serrated pattern of pemphigoid.¹⁴⁰² IgM was the only deposit in one case.¹⁴⁰³ Circulating IgG class antibodies to the basement membrane zone are present in up to 50% of cases.^{1404,1405} IgA autoantibodies have been detected in a significant number of cases.¹⁴⁰⁶ They may also occur in childhood cases.¹³⁸⁹ When salt-split skin is used as a substrate, these antibodies bind to the dermal floor, in contrast to bullous pemphigoid antibodies, which bind to the epidermal roof.¹⁴⁰⁷ Some doubts have been expressed about the reliability of this technique in the diagnosis of EBA.^{1408,1409} The presence of epidermal-binding antibodies, which are sometimes found in EBA, may be a consequence of epitope spreading – a phenomenon observed in other immunobullous diseases.^{1410,1411} In one case, antibodies to laminin α_3 were detected in addition to the usual antibodies to type VII collagen.¹⁴¹¹ The site of the deposits can be determined by the fluorescence overlay antigen mapping (FOAM) technique, although this is a more complex technique than the salt-split skin method.¹⁴¹² The FOAM technique has also been successfully adapted for use with laser scanning confocal microscopy.¹⁴¹³

Electron microscopy

The split usually occurs in the superficial dermis below the lamina lucida.¹⁴¹⁴ In some of the inflammatory variants, however, splitting may occur within the lamina lucida, possibly as a result of leukocyte-derived proteolytic enzymes acting on the lamina lucida, which appears to be a *locus minoris resistentiae*.^{1415,1416} Electron-dense amorphous deposits are present beneath the lamina densa. On immunoelectron microscopy, the immunoreactants that correspond with the electron-dense deposits noted on routine electron microscopy are found within and/or below the lamina densa, sometimes covering the anchoring fibrils.^{1340,1416–1418} In one report, the site of the deposits varied depending on whether pre-embedding or postembedding immunogold techniques were used.¹⁴¹⁹

Figure 6.20 Porphyria cutanea tarda. There is a cell-poor, subepidermal bulla with preservation of the dermal papillae in the floor ('festooning'). (Periodic acid-Schiff)

PORPHYRIA CUTANEA TARDA

Blisters can develop in light-exposed areas, particularly the dorsum of the hands, in porphyria cutanea tarda.

Histopathology

The blisters are subepidermal, with preservation of the dermal papillae in the floor of the lesion ('festooning'; [Fig. 6.20](#)). Hyaline material, which is PAS positive and diastase resistant, is present in the walls of the small vessels in the upper dermis and sometimes in the basement membrane of the epidermis. There is usually no inflammatory infiltrate, although patchy hemorrhage is sometimes present in the blister and the underlying dermis.

BULLOUS PEMPHIGOID (CELL-POOR TYPE)

If a biopsy is taken from a bullous lesion in bullous pemphigoid that does not have an erythematous base, the lesion will often have few inflammatory cells in the dermis. This is in contrast to lesions with an erythematous base that usually have a heavier dermal infiltrate, including many eosinophils.

BURNS AND CRYOTHERAPY

Subepidermal blisters may develop in second-degree thermal burns and following electrodesiccation therapy. Rarely, thermal burns are produced by a high-intensity fiber-optic light source used in transillumination for the diagnosis of pneumothorax.¹⁴²⁰ Delayed postburn blisters may develop months after the initial burn.¹⁴²¹ They are subepidermal in type. A bullous pemphigoid-like eruption has also been reported after a chemical burn.¹⁴²² Hemorrhagic blisters may develop after cryotherapy (see p. 618). They are usually cell-poor initially; neutrophils may be present in older lesions, particularly if the lesion becomes infected. Bullous dermatitis artefacta, probably produced by an aerosol spray resulting in cryoinjury, has been reported.¹⁴²³

The epidermis is usually necrotic; vertical elongation of keratinocytes is a conspicuous feature after electrodesiccation. The basket-weave pattern of the stratum corneum is usually preserved. A distinctive feature of burns and electrodesiccation is the fusion of

Figure 6.21 Toxic epidermal necrolysis. This lesion is characterized by a cell-poor, subepidermal blister with necrosis of the overlying epidermis. There is a surviving sweat duct in the base of the blister. (H&E)

collagen bundles in the upper dermis; they have a refractile eosinophilic appearance.

TOXIC EPIDERMAL NECROLYSIS

Toxic epidermal necrolysis, which is now regarded as the most severe form of an erythema multiforme spectrum, presents with generalized tender erythema that rapidly progresses to a blistering phase with extensive shedding of the skin. There is a subepidermal bulla with confluent necrosis of the overlying epidermis ([Fig. 6.21](#)). The perivascular infiltrate of lymphocytes, if present at all, is usually sparse, justifying categorization of the condition as a cell-poor blistering disease. Cases with features overlapping those of erythema multiforme are sometimes seen.

Mustard gas, used in chemical warfare, can result in bullae with full-thickness epidermal necrosis resembling toxic epidermal necrolysis.¹⁴²⁴ In the early stages, the epidermal keratinocytes are swollen and hydropic; many have pyknotic nuclei.^{1425,1426}

Sometimes, **chemotherapy-induced acral erythema** can progress to a subepidermal bullous lesion with epidermal necrosis.^{1427,1428}

Figure 6.22 Subepidermal clefting overlying scar tissue. (H&E)

SUCTION BLISTERS

Blisters induced by suction are subepidermal in type, in contrast to friction blisters that develop within the epidermis. The dermal papillae are usually preserved in suction blisters ('festooning'). Suction blisters may be a manifestation of dermatitis artefacta. They are also seen following the Oriental tradition of cupping, which involves the therapeutic application of heated cups to the skin.¹⁴²⁹

BLISTERS OVERLYING SCARS

Subepidermal clefting sometimes occurs overlying a dermal scar, particularly if this involves the papillary as well as the reticular dermis. The clefting is usually an incidental histological finding without obvious clinical manifestations. The finding of scar tissue in the base of the blister in association with a clinical history of surgery or some other trauma at the affected site characterizes this entity (Fig. 6.22).

Subepidermal bullae, with a slight lymphocytic infiltrate, have been reported in grafted leg ulcers 4–8 weeks after the operation.¹⁴³⁰ The pathogenetic mechanism is not known.

A subepidermal blister overlay the necrotic tissue in a neonate with congenital Volkmann's ischemic contracture.¹⁴³¹ Such lesions may mimic aplasia cutis, amniotic band syndrome, and epidermolysis bullosa.

BULLOUS SOLAR ELASTOSIS

The blisters that occur rarely in areas of severe solar elastosis are intradermal rather than subepidermal. A thin grenz zone of papillary dermis overlies them.^{1432,1433}

BULLOUS AMYLOIDOSIS

Rarely, bullae may form above the amyloid deposits in the skin in primary systemic amyloidosis (see p. 433). The split is usually in the upper dermis. There are characteristic hyaline deposits of amyloid in the base of the blister. Hemorrhage is often present. Electron microscopy shows that keratinocytes enfold the amyloid globules and take them into the intercellular space of the epidermis, where the amyloid globules then widen, producing disruption of attachments and the lamina densa.¹⁴³⁴

A poikilodermatous, bullous form of amyloidosis, with the split at the level of the lamina lucida, has been reported.¹⁴³⁵

WALDENSTRÖM'S MACROGLOBULINEMIA

A subepidermal bullous dermatosis is a rare manifestation of Waldenström's macroglobulinemia.^{1436,1437} Extreme skin fragility is often present in these patients.¹⁴³⁸ Monotypic IgM deposits along the basement membrane.¹⁴³⁸ The deposits are in the lamina densa. Infiltration of the skin with neoplastic B cells is a rare manifestation of this disease.^{1439,1440}

Oral corticosteroid has cleared the lesions in several cases.¹⁴³⁸ Remission was obtained in one case with oral cyclophosphamide.¹⁴³⁹

BULLOUS DRUG REACTION

Subepidermal bullae are an uncommon manifestation of a drug reaction. They have been reported in a patient taking the complementary medicine guggulipid.¹⁴⁴¹ A drug reaction that developed after several months of fluvoxamine therapy combined a subepidermal blister with some intraepidermal vesiculation.¹⁴⁴² The inflammatory cell infiltrate in the dermis may be variable in intensity and composition. One category is cell poor and resembles porphyria cutanea tarda (pseudoporphyria).

In contrast to porphyria cutanea tarda, drug-induced pseudoporphyria has less PAS-positive material in vessel walls and less obvious 'festooning' (persistence of dermal papillae in the base of the blister). A rare eosinophil may be present in the dermis in the drug-induced cases; this is not a feature of porphyria cutanea tarda. Blisters resembling pseudoporphyria can be seen in a palmoplantar distribution in patients undergoing hemodialysis.¹⁴⁴³

Cell-poor subepidermal bullae have been reported following the infusion of ε-aminocaproic acid.¹⁴⁴⁴ Fibrin thrombi were present in vessels in the papillary dermis. No histology was done on a bullous skin eruption thought to have been induced by entacapone, a drug used in the treatment of Parkinson's disease.¹⁴⁴⁵ Also mentioned here is the bullous reaction produced by the weight-management drug sibutramine. Although it gave an erythema multiforme-like rash, the histological changes were not those of this disease.¹⁴⁴⁶

This is a convenient place to tabulate all drugs producing a vesiculobullous pattern (Table 6.4). Specific references are included in the text in the appropriate section of this chapter.

KINDLER'S SYNDROME

Kindler's syndrome (OMIM 173650), a poikilodermatous genodermatosis, is characterized by bullae that are subepidermal and cell poor (see p. 76). It results from mutations in the *KIND1* gene that encodes a protein that binds actin microfilaments to the extracellular matrix. Ultrastructural studies have shown that the split can occur at several levels within the dermoepidermal junction zone, including within the basal cells. It has been regarded as the fourth major subtype of epidermolysis bullosa in the recent reclassification of this disease.⁹⁴¹

SUBEPIDERMAL BLISTERS WITH LYMPHOCYTES

All of the conditions in this group, with the exception of paraneoplastic pemphigus, are discussed in other chapters. Accordingly, these other conditions will be given only brief mention here.

Table 6.4 Drugs causing vesiculobullous and pustular reactions

Subcorneal pustular dermatosis-like: amoxicillin, cephalosporins, dapsone, diltiazem, gefitinib, isoniazid, paclitaxel, quinidine
Acute generalized exanthematous pustulosis: see Table 6.2 for complete listing
Pemphigus foliaceus and erythematous: aspirin, bucillamine, captopril, ceftazidime, cephalosporins, enalapril, fosinopril, gold, heroin, imiquimod, levodopa, methimazole, penicillamine, propranolol, pyritinol, ramipril, rifampin (rifampicin), tetanus vaccination, thiol-containing drugs, thiopronine
Pemphigus vulgaris and vegetans: ampicillin, anthrax vaccine, captopril, cilazapril, ciprofloxacin, cocaine snorting, diclofenac, dipyrone, enalapril, fosinopril, heroin, hydroxychloroquine, influenza immunization, interleukin-2, ketoprofen, nifedipine, norfloxacin, penicillamine, penicillin, phenols, quinapril, rifampin (rifampicin), tannins, tetanus and diphtheria vaccine, thiol-containing foods, typhoid immunization
Subepidermal (cell poor) – pseudoporphyria: acitretin, amiodarone, ampicillin-sulbactam, aspirin, β -lactams, bumetanide, cefepime (?), celecoxib, chlorthalidone, ciprofloxacin, cola consumption, contraceptive pill, cyclosporine (ciclosporin), etretinate, 5-fluorouracil, flutamide, furosemide (frusemide), hemodialysis, imatinib, isotretinoin, ketoprofen, mefenamic acid, metformin, nabumetone, nalidixic acid, naproxen, oxaprozin, pravastatin, pyridoxine, rofecoxib, sulfonamides, tanning beds, tetracyclines, UVB phototherapy, voriconazole
Subepidermal (lymphocytes $\pm$ eosinophils) – erythema multiforme/TEN: acarbose, allopurinol, amifostine, aminopenicillins, bezafibrate, cannabis, carbamazepine, ceftazidime, celecoxib, chloroquine, cimetidine, ciprofloxacin, clindamycin, clobazam, clonazepam, cocaine, cyclophosphamide, cytosine arabinoside, diacerein, doxycycline, ethambutol, etretinate, famotidine, gemeprost, griseofulvin, imiquamod cream, indapamide, indomethacin, isoxicam, lamotrigine, latanoprost eye drops, mefloquine, methotrexate, mifepristone, nevirapine, nitrogen mustard, nystatin, oxaprozin, phenylbutazone, phenytoin, piroxicam, pravastatin, ranitidine, ritodrine, sertraline, simvastatin, sorafenib, sulfamethoxazole, suramin, terbinafine, theophylline, ticlopidine, trichloroethylene, trimethoprim, valproic acid, vancomycin
Subepidermal (eosinophils) – bullous pemphigoid: 5-aminosalicylic acid, amlodipine, ampicillin, antipsychotic drugs, aspirin, bumetanide, captopril, cephalixin, chloroquine, ciprofloxacin, doxazosin, efalizumab, enalapril, enoxaparin, erlotinib, etanercept, fluorouracil (topical), fluoxetine, furosemide (frusemide), gabapentin, ibuprofen, influenza immunization, iodine (intravenous), levobunolol (ophthalmic), levofloxacin, lisinopril, losartan, metformin and gliptins (dipeptidyl peptidase IV inhibitors), neuroleptics, nifedipine, novoscabin, penicillamine, penicillin and derivatives, serratiopeptidase, sulfasalazine, tetanus immunization
Subepidermal (neutrophils) – linear IgA bullous dermatosis: acetaminophen (paracetamol), amiodarone, amlodipine, amoxicillin, ampicillin/sulbactam, atorvastatin, captopril, carbamazepine, cefamandole, ceftriaxone, diclofenac, furosemide (frusemide), glibenclamide, interleukin-2, lithium carbonate, metronidazole, naproxen, penicillin, phenytoin, piroxicam, sodium hypochlorite (contact), somatostatin, trimethoprim-sulfamethoxazole, ustekinumab, vancomycin, verapamil
Subepidermal (scarring) – mucous membrane pemphigoid: atenolol, azathioprine, clonidine, practolol
Subepidermal (vasculitis): some of the drugs producing a leukocytoclastic vasculitis (see Chapter 8) may result in blister formation, but this is not a consistent feature of any particular drug
Subepidermal (necrosis) – drug overdose-related bullae: amitriptyline, barbiturates, carbamazepine, clobazam, diazepam, heroin, imipramine, methadone, morphine

ERYTHEMA MULTIFORME

The vesiculobullous lesions in erythema multiforme result from damage to the basal cells of the epidermis. Accordingly, this condition is considered among the lichenoid reaction patterns (see Chapter 3, p. 56). Erythema multiforme is characterized by a subepidermal blister

with a mild to moderately heavy infiltrate of lymphocytes in the underlying dermis. The infiltrate, which may include a few eosinophils, extends to the level of the mid dermis. The epidermis overlying the blister may show necrosis that may be confluent or involve only small groups of cells. Apoptotic keratinocytes are usually present in the epidermis adjacent to the blister.

PARANEOPLASTIC PEMPHIGUS

Paraneoplastic pemphigus is an autoimmune blistering disorder characterized by polymorphous skin lesions with features of both erythema multiforme and pemphigus vulgaris in association with internal neoplasms, especially non-Hodgkin's lymphoma.¹⁴⁴⁷⁻¹⁴⁵² Included in this category are cases of CD20⁺ follicular lymphomas,¹⁴⁵³ CD8⁺ cytotoxic T-cell lymphoma,¹⁴⁵⁴ NK/T-cell lymphoma,¹⁴⁵⁵ and diffuse large B-cell lymphoma.¹⁴⁵⁶ Several patients with chronic lymphocytic leukemia treated with fludarabine have developed paraneoplastic pemphigus.^{1457,1458} Other associations have included Hodgkin's disease,¹⁴⁵⁹ thymoma,^{1460,1461} hepatocellular carcinoma,¹⁴⁶² malignant fibrous histiocytoma,¹⁴⁶³ inflammatory myofibroblastic tumor,¹⁴⁶⁴ follicular dendritic cell sarcoma,¹⁴⁶⁵⁻¹⁴⁶⁷ Waldenström's macroglobulinemia,¹⁴⁶⁸ untreated B-cell lymphocytic leukemia,^{1469,1470} uterine carcinoma,¹⁴⁷¹ Castleman's disease,¹⁴⁷²⁻¹⁴⁸¹ malignant gastrointestinal stromal tumor,¹⁴⁸² and esophageal squamous cell carcinoma.¹⁴⁸³ Paraneoplastic pemphigus can precede the diagnosis of malignancy, particularly in patients who develop Castleman's disease, or it may develop many years after the development of the tumor. It is not related to the tumor burden of a particular patient.¹⁴⁸⁴ It is not restricted to adults. Children and adolescents may develop the disease.¹⁴⁸⁵ Since its original description, the clinical and immunopathological spectrum of paraneoplastic pemphigus has expanded. At least seven clinical variants are now recognized:

- Erythema multiforme-like¹⁴⁸⁶
- Pemphigoid-like¹⁴⁸⁷⁻¹⁴⁹⁰
- Pemphigus-like (foliaceus, vulgaris, and vegetans)^{1491,1492}
- Graft-versus-host disease (GVHD)-like¹⁴⁹³
- Lichen planus pemphigoides- or (erosive) lichen planus-like¹⁴⁹⁴⁻¹⁵⁰⁰
- Cicatricial pemphigoid-like^{1501,1502}
- Linear IgA dermatosis-like.¹⁵⁰³

Unusual presentations have included onset following systemic interferon¹⁵⁰⁴ or radiotherapy,¹⁵⁰⁵ localization to a radiation field,¹⁴⁴⁷ elevated levels of IL-6,¹⁵⁰⁶ onset in childhood or adolescence,^{1507,1508} overlap with IgA pemphigus,¹⁵⁰⁹ the presence of annular lesions,¹⁵¹⁰ and the absence of a detectable neoplasm.¹⁵¹¹⁻¹⁵¹⁴ One case progressed eventually to pemphigus vulgaris.¹⁵¹⁵ Other features of this condition include the presence of mucosal erosions, pseudomembranous conjunctivitis, corneal melting, or severe pulmonary involvement, particularly bronchiolitis obliterans, that may lead to respiratory failure.^{1473,1516,1517} One patient with three malignancies (thyroid carcinoma, clear cell carcinoma of the kidney, and follicular dendritic cell sarcoma) had paraneoplastic pemphigus and anti-laminin-332 mucous membrane pemphigoid.¹⁵¹⁸ Patients with paraneoplastic pemphigus usually have a poor prognosis, although several cases of prolonged survival have been reported.^{1519,1520} In one small study, fatal cases were associated with cell surface antibodies detected by complement indirect immunofluorescent tests on monkey esophagus, whereas several survivors did not have these antibodies.¹⁵²¹

Antibodies have been detected to multiple antigens, including members of the plakins family as well as the desmogleins. Three or more antibodies are often present in the same patient.¹⁴⁷⁹ Specifically, they include the following:

- Desmoplakin 1 (250 kDa)
- Desmoplakin 2
- Envoplakin (210 kDa)^{1522,1523}
- Bullous pemphigoid antigen (230 kDa)
- Periplakin (190 kDa)^{1524–1526}
- Desmocollins 2 and 3¹⁵²³
- γ -Catenin (plakoglobin; 82 kDa)¹⁵²⁷
- Plectin (500 kDa)^{1528,1529}
- α_2 -Macroglobulin-like-1 (protease inhibitor; 170 kDa)¹⁵³⁰
- Desmogleins 1 and 3^{1466,1531–1533}
- Plakophilin-3 (84 and 115 kDa).¹⁵³⁴

Antibodies to one or both of the desmogleins are usually, but not always, present.¹⁵³⁵ Whereas in pemphigus vulgaris the dominant IgG subclass against dsG3 is IgG4, in paraneoplastic pemphigus the response against dsG3 is more diversified and the IgG subclass is IgG1 and IgG2.¹⁵³⁶ Epitope spreading is probably responsible for the diversity of the antibodies and the clinicopathological changes.^{1537,1538} The B cells isolated from a diverse range of tumors associated with paraneoplastic pemphigus can produce autoantibodies that can recognize various antigens in the epidermis.¹⁴⁸⁰ Somatic mutations occur in the genes in these B lymphocytes that produce the various autoantibodies.¹⁵³⁹ In several cases, all treated with rituximab, autoantibodies have not been detectable.^{1499,1540} The initial lichenoid reaction may promote the exposure of self-antigens and the development of subsequent and progressive humoral autoimmunity.¹⁵³⁸ The diversity of autoantibodies that may deposit in the skin, lungs, and other organs, and the damage that these antibodies may produce, has led to the suggestion of the encompassing term ‘paraneoplastic autoimmune multiorgan syndrome’ or PAMS.^{1496,1541}

In addition to this humoral component, there appears to be a contribution of cytotoxic T lymphocytes to the pathogenesis.¹⁴⁹³

There is some immunogenetic susceptibility in paraneoplastic pemphigus. HLA-Cw*14 is one predisposing allele in Chinese patients, but it is not the allele responsible in other races.¹⁵⁴²

Paraneoplastic pemphigus is resistant to most therapies, but initially, treatment is aimed at the underlying malignancy in an attempt to control the autoantibody production.¹⁴⁵³ Treatments used, depending to some extent on the nature of the tumor, have included high-dose corticosteroids, azathioprine, cyclosporine, photopheresis, mycophenolate mofetil, and intravenous immunoglobulin.¹⁴⁶⁹ Rituximab, a CD20 monoclonal antibody, has been used to treat cases with an underlying CD20⁺ lymphoma. It has been useful in some cases¹⁵⁴³ but not in others.¹⁴⁵³ Alemtuzumab has been effective in the treatment of severe chronic lymphocytic leukemia-associated paraneoplastic pemphigus.¹⁵⁴⁴

Histopathology

The histological features are variable, reflecting the polymorphous clinical features (Fig. 6.23). There is usually a lichenoid tissue reaction (interface dermatitis) with exocytosis of lymphocytes, apoptotic (dyskeratotic) keratinocytes, and basal vacuolar change. These features are usually combined with suprabasal acantholysis and clefting, but this change is not invariably found even when multiple sections are examined.^{1545–1547} In a large French series that included 53 patients with paraneoplastic pemphigus, erythema multiforme-like skin lesions and keratinocyte necrosis were associated with an adverse prognosis and rapidly fatal outcome.¹⁵⁴⁸ In one study, 27% of cases had suprabasal acantholysis alone.¹⁵⁴⁹ Focal epidermal spongiosis is often present. Subepidermal clefting is uncommonly a major feature. Rarely, verrucous lesions with acanthosis and papillomatosis have been seen. Suprabasal acantholysis has been seen in a malignant melanoma. The authors suggested that this was a localized variant of paraneoplastic pemphigus.¹⁵⁵⁰

Figure 6.23 Paraneoplastic pemphigus. There are erythema multiforme-like changes in one area and pemphigus vulgaris-like changes in others. (H&E)

The dermal infiltrate is often heavy and band-like, although there is usually some extension of the infiltrate into the reticular dermis. Most of the cells are lymphocytes, but occasional eosinophils and neutrophils may also be present.¹⁵⁵¹ Infiltrates within epithelia include CD8⁺ T-cells and CD68⁺ macrophages.¹⁵⁵²

Direct IF shows intercellular and basement membrane staining with C3 and/or IgG, reminiscent of pemphigus erythematosus.^{1551,1553} Indirect IF using murine bladder epithelium shows intercellular staining of the epithelium.¹⁵⁵⁴ This test was originally regarded as highly specific and sensitive, although one study has reported negative findings in nearly 25% of cases.¹⁵⁵⁵ Furthermore, as mentioned previously, positive results with this substrate are also sometimes obtained in cases of pemphigus vulgaris and pemphigus foliaceus.²⁰⁹

FIXED DRUG ERUPTIONS

A bullous variant of fixed drug eruption has been described. The lesions resemble those seen in erythema multiforme; in fixed drug eruptions, there is usually deeper extension of the inflammatory cell infiltrate in the dermis, with more eosinophils and sometimes neutrophils in the infiltrate, and melanin in macrophages and lying free in the upper dermis. The inflammatory cell infiltrate tends to obscure the dermoepidermal interface (interface dermatitis) adjacent to the blister in both erythema multiforme and fixed drug eruptions.

LICHEN SCLEROSUS ET ATROPHICUS

Lichen sclerosis et atrophicus is a chronic dermatosis affecting predominantly the anogenital region of middle-aged and elderly women. Infrequently, hemorrhagic bullae develop. There is a broad zone of edema or partly sclerotic collagen in the base of the blister with telangiectatic vessels and some hemorrhage. Beneath this edematous/sclerotic zone, there is an infiltrate of lymphocytes that is predominantly *perivascular* in position.

LICHEN PLANUS PEMPHIGOIDES

Lichen planus pemphigoides is characterized by the development of tense blisters, often located on the extremities, in a patient with lichen planus. There is a mild perivascular infiltrate of lymphocytes, and sometimes there are a few eosinophils and neutrophils beneath the

blister. Occasional Civatte bodies are usually present in the basal layer at the margins of the blister. Direct IF will usually demonstrate IgG and C3 in the basement membrane zone. It needs to be distinguished from *vesiculobullous dermatomyositis*, in which a subepidermal blister occurs with a small number of lymphocytes in the upper dermis. Interface (lichenoid) changes are usually very mild in this condition, in contrast to lichen planus pemphigoides.¹⁵⁵⁶

If the bullae develop in papules of lichen planus, as opposed to otherwise uninvolved skin, there is usually a much heavier dermal infiltrate that is superficial and band-like in distribution. There are numerous Civatte bodies in the overlying and adjacent basal keratinocytes. The term 'bullous lichen planus' is used in these circumstances.

POLYMORPHIC LIGHT ERUPTION

Papulovesicular lesions and, rarely, bullae may occur as a clinical subset of polymorphic light eruption. The lesions develop several hours after exposure to the sun. There is pronounced subepidermal edema leading to blister formation. In early lesions, the collagen fibers are separated by the edema fluid, giving a cobweb-like appearance. Extravasation of red blood cells may be present in this region. A characteristic feature is the presence of a perivascular infiltrate of lymphocytes that involves not only the superficial dermis but also the deep dermis.

FUNGAL INFECTIONS

Pronounced subepidermal edema leading to vesiculation is a rare manifestation of a fungal infection. It may also be seen in the autoeczematous reaction ('id reaction') to a fungus (see p. 127).

DERMAL ALLERGIC CONTACT DERMATITIS

This poorly understood variant of allergic contact dermatitis may result from contact with various agents, particularly neomycin, and zinc and nickel salts. There is pronounced subepidermal edema leading to vesiculation. The lymphocytes in the infiltrate do not extend as deeply in the dermis as they do in polymorphic light eruption. Epidermal spongiosis is often present, and it distinguishes this condition from the other subepidermal blistering diseases.

BULLOUS LEPROSY

Subepidermal bullae are an exceedingly rare manifestation of borderline lepromatous leprosy. Lymphocytes and small collections of macrophages, some with foamy cytoplasm, are present in the dermis; they also surround small cutaneous nerves. Acid-fast bacilli are present within the macrophages.

BULLOUS MYCOSIS FUNGOIDES

Bullae are a very rare manifestation of mycosis fungoides. They are usually subepidermal in location, but intraepidermal splitting has been recorded (see p. 1177). The presence of atypical lymphocytes in the underlying dermis and of Pautrier microabscesses in the epidermis characterizes this condition.

SUBEPIDERMAL BLISTERS WITH EOSINOPHILS

Eosinophils are a conspicuous and major component of the inflammatory cell infiltrate in the bullae and in the dermis in bullous pemphigoid

and pemphigoid gestationis. They are also found in certain arthropod bite reactions, particularly in sensitized individuals, and in some bullous drug reactions. Vesiculobullous lesions, resembling insect bites, have been reported in patients with chronic lymphocytic leukemia.¹⁵⁵⁷ Eosinophils may be the predominant cell type in some cases of dermatitis herpetiformis (particularly lesions that are more than 48 hours old) and of cicatricial pemphigoid. They are also present in the subepidermal blisters that sometimes develop in Wells' syndrome (see p. 1132).

BULLOUS PEMPHIGOID

Bullous pemphigoid is a chronic subepidermal blistering disease that occurs primarily in the elderly.¹⁵⁵⁸⁻¹⁵⁶⁰ It is the most common subepidermal bullous disease with an annual incidence, in a large French series, of seven cases per 1,000,000 people.¹⁵⁶¹ It accounts for approximately 80% of all subepidermal autoimmune bullous diseases.^{1562,1563} Multiple, tense bullae of varying size develop on normal or erythematous skin. Individual lesions may measure several centimeters in diameter. In addition, there may be erythematous macules, urticarial plaques, papules, and crusted erosions.^{1564,1565} Annular lesions have been reported.¹⁵⁶⁶ Eczematous or urticarial lesions, usually pruritic, may precede by weeks or months the occurrence of bullous lesions (prodromal bullous pemphigoid).¹⁵⁶⁷⁻¹⁵⁷⁰ Rarely, this prodromal phase of bullous pemphigoid does not progress to a blistering stage.^{1571,1572} In one study, up to 20% of patients lacked obvious blistering.¹⁵⁷³ Uncommon presentations of bullous pemphigoid include as an erythroderma¹⁵⁷⁴⁻¹⁵⁷⁷ or as a figurate erythema;¹⁵⁷⁸⁻¹⁵⁸⁰ the development of lesions localized to one area of the body,¹⁵⁸¹ such as the vulva,¹⁵⁸²⁻¹⁵⁸⁴ the legs (particularly the pretibial skin),¹⁵⁸⁵⁻¹⁵⁹⁰ the paralyzed side in hemiplegia,¹⁵⁹¹ a stoma site,¹⁵⁹²⁻¹⁵⁹⁴ initially at a stoma site with later generalization,²⁴ or the palms and soles;^{1595,1596} and the development of a hemorrhagic pompholyx (dyshidrosiform pemphigoid).¹⁵⁹⁷⁻¹⁶⁰¹ Nail loss may occur.^{1602,1603} There is a rare case with tracheobronchial involvement.¹⁶⁰⁴

The localized variants of bullous pemphigoid must be distinguished from localized cicatricial pemphigoid in which scarring occurs (see p. 184) and from acute edema blisters that may form on the legs in association with rapidly developing edema.^{1605,1606} It is uncertain whether all cases of 'localized pemphigoid' are variants of bullous pemphigoid: underlying vascular disease and lymphatic obstruction have been present in some cases in the pretibial region.¹⁶⁰⁶ Furthermore, direct IF is sometimes negative in these cases.¹⁶⁰⁶ The author has seen several such cases; it appears to be a 'neglected' entity. Pretibial epidermolysis bullosa also needs to be considered in these circumstances; it usually presents in the first three decades of life. Diagnosis is often delayed in cases of localized disease.¹⁵⁷³

In established cases of bullous pemphigoid, bullae are found on the lower part of the abdomen, in the groins, and on the flexor surface of the arms and legs. Oral lesions are present in 10-40% of cases, but involvement of other mucosal surfaces is quite rare.¹⁶⁰⁷⁻¹⁶⁰⁹ Eosinophilia in the blood and elevated serum IgE and eosinophil cationic protein levels are often present.^{1564,1610-1612} Elevated IgE levels have been associated with an adverse outcome in some series¹⁶¹³ but not others.¹⁶¹⁴

The disease tends to involve older people,^{1564,1615} but its occurrence in young adults¹⁶¹⁶ and in children has been reported.¹⁶¹⁷⁻¹⁶²⁵ Two subtypes of childhood bullous pemphigoid occur: infantile bullous pemphigoid, which is characterized by bullous lesions on erythematous or normal acral skin in the first year of life,^{1626,1627} and localized vulval bullous pemphigoid, a self-limited, nonscarring bullous pemphigoid-like process that involves only the vulva.¹⁶²⁸ Because childhood disease may mimic other bullous disorders, the diagnosis requires direct IF and sometimes characterization of the target antigen as well.¹⁶²⁸ IgA antibodies against the NC16A domain of BP180 have also been detected in some childhood cases, raising questions about the relationship of these cases to linear IgA bullous dermatosis.¹⁶²⁹ Bullous

pemphigoid of infancy is not due to materno-fetal transfer of pathogenic autoantibodies.¹⁶³⁰

An association with HLA-DQ7 has been reported in men.¹⁶³¹ The possession of the DR8 and DR8/DQ6 haplotypes appeared to have a protective role in bullous pemphigoid patients from northern China.¹⁶³² Gene polymorphisms in the cytokine gene for IL-1 β have been found in women with bullous pemphigoid in a Chinese population.¹⁶³³

Several rare clinical variants of bullous pemphigoid have been reported (see later). Immunoelectron microscopy of these variants has shown that the immunoreactants deposit in the same position in the basement zone as they do in bullous pemphigoid; this justifies their inclusion as variants of bullous pemphigoid.^{1588,1634,1635}

Vesicular pemphigoid

There is a chronic eruption of small vesicles that are often pruritic and occasionally grouped, resembling dermatitis herpetiformis.^{1636–1638} Progression to typical bullous pemphigoid sometimes occurs.¹⁶³⁶ Autoantibodies in this variant can be heterogeneous.^{1639,1640} In one case, they were to plectin,¹⁶⁴¹ in another to desmoplakin,¹⁶⁴² and in a further case they were to 230-, 180-, 97-, and 45-kDa proteins.¹⁶⁴³

Pemphigoid vegetans

Pemphigoid vegetans is a rare variant that resembles pemphigus vegetans clinically with purulent and verrucous vegetating lesions in intertriginous areas, particularly the groins.^{1644–1648} Inflammatory bowel disease is usually present in patients with this form of bullous pemphigoid.¹⁶⁴⁴ The autoantibodies, which are primarily in the IgG4 subclass, react with the 230-kDa major bullous pemphigoid antigen.¹⁶⁴⁷ Autoantibodies against both 230- and 180-kDa antigens have been found in a case.¹⁶⁴⁹

Polymorphic pemphigoid

This term 'polymorphic pemphigoid' has been used for cases with features of both dermatitis herpetiformis and bullous pemphigoid.^{1650,1651} Some of these cases would now be regarded as examples of linear IgA disease.¹⁶⁵² The probable coexistence of bullous pemphigoid and dermatitis herpetiformis has also been reported.¹⁶⁵³

Pemphigoid excoriée

The term 'pemphigoid excoriée' was given to a case in which the bullae were localized to areas of chronic excoriation.¹⁶⁵⁴

Pemphigoid nodularis

Pemphigoid nodularis is a rare variant combining features of prurigo nodularis with those of bullous pemphigoid, often in the same lesion.^{1586,1655–1658} They have the same autoantibodies as bullous pemphigoid.^{1659,1660} The verrucous papules or nodules may persist or resolve with scarring. Sometimes the nodules precede the onset of blisters by several months.¹⁶⁶¹ Nonbullous variants with circulating and tissue-bound autoantibodies to BP180 and BP230 have been reported.¹⁶⁶² A case with hyperkeratotic islands within areas of denuded blisters, reported as 'pemphigoid en cocarde', is best regarded as a variant of pemphigoid nodularis.¹⁶⁶³ In one patient, lichen planus pemphigoides evolved into pemphigoid nodularis.¹⁶⁶⁴ Pemphigoid nodularis developed in a teenage boy with IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome (OMIM 304790) caused by a mutation in the *FOXP3* gene on chromosome Xp11.23–q13.3.¹⁶⁶⁵ It has also been associated with psoriatic erythroderma.¹⁶⁶⁶

A wide range of diseases, many of presumed autoimmune origin, is reported in association with bullous pemphigoid.¹⁶⁶⁷ They include rheumatoid arthritis,¹⁶⁶⁸ SLE,^{1669–1671} dermatomyositis,¹⁶⁷² primary biliary cirrhosis,¹⁶⁷³ ulcerative colitis,¹⁶⁷⁴ alopecia areata,¹⁶⁷⁵ diabetes mellitus,¹⁶⁷⁶ thyroid disease,^{1677,1678} multiple sclerosis,^{1679,1680} amyotrophic lateral sclerosis,¹⁶⁸¹ leukocytoclastic vasculitis,¹⁶⁸² a myelodysplastic syndrome,¹⁶⁸³ hypereosinophilic syndrome,¹⁶⁸⁴ hyperimmunoglobulin E syndrome,¹⁶⁸⁵

silicosis,¹⁶⁸⁶ neurofibromatosis,¹⁶⁸⁷ C4 deficiency,¹⁶⁸⁸ autoimmune thrombocytopenia,¹⁶⁸⁹ acanthosis palmaris,¹⁶⁹⁰ immune complex nephritis,^{1691–1693} pemphigus,¹⁶⁹⁴ psoriasis,^{1695–1698} mantle cell lymphoma,¹⁶⁹⁹ and internal or cutaneous cancer.^{1672,1700–1706} It now appears, however, that the association of bullous pemphigoid with autoimmune diseases and with internal cancer is not statistically significant.^{1707,1708} Because bullous pemphigoid affects older individuals, pregnancy is an uncommon association.¹⁷⁰⁹ A number of studies have indicated an association with neurologic diseases, including stroke, dementia, Parkinson's disease, epilepsy, and schizophrenia, in some cases reaching statistical significance.^{1710–1713} These conditions frequently occur prior to the onset of pemphigoid.¹⁷¹⁰ In this regard, it is interesting to note that both bullous pemphigoid antigens (230 and 180 kDa) are expressed in the central nervous system.¹⁷¹⁴ Immobility or age-related autoimmunity may be important factors in these disease associations.¹⁷¹¹

Bullous pemphigoid runs a chronic course of months to years, with periods of remission and exacerbation.⁶⁷⁸ Left untreated, there is significant morbidity with often intractable pruritus, and bullous eroded skin.¹⁷¹⁵ Death is now uncommon in this disease because of improved management.^{678,1716} Death is more likely in elderly patients with extensive disease and in those with antibodies to BP180 (see later).¹⁷¹⁷ Low serum albumin levels, old age, and treatment with high doses of corticosteroids are risk factors for a lethal outcome.¹⁷¹⁸ In a French study in 2005, older age was associated with a poorer prognosis, but no factors directly related to the disease, such as the extent of the lesions, influenced prognosis.¹⁷¹⁹

Pathogenesis

The initial event in the pathogenesis of bullous pemphigoid appears to be the binding of autoantibodies to a transmembrane antigen associated with the lamina lucida and the hemidesmosomes of basal keratinocytes (the bullous pemphigoid antigen).^{1720–1724} The bullous pemphigoid antigen shows molecular heterogeneity.^{1559,1725–1728} one antigen (BP230, BPAg1) is a 230-kDa polypeptide that is assembled in macromolecular aggregates within the hemidesmosomes;^{1729,1730} the other (BP180, BPAg2) is a 180-kDa transmembrane glycoprotein with both intracellular and extracellular relationships with the hemidesmosomes.^{1731–1733}

BP180 consists of an intracellular N-terminal portion, a transmembrane region, and a long collagenous extracellular domain (type XVII collagen) that spans the lamina lucida and extends to the lamina densa.¹⁷³⁴ Collagen XVII is a collagenous transmembrane protein and a structural component of the dermoepidermal anchoring complex. It functions as a cell–matrix adhesion molecule through stabilization of the hemidesmosome complex.¹⁷³⁵ A noncollagenous stretch of this ectodomain, designated NC16A, harbors four major epitopes recognized by serum samples from patients with bullous pemphigoid.^{1736–1738} A portion of the extracellular domain of BP180 is identical to an antigen found in linear IgA bullous dermatosis, LABD97. Antibodies may occur to this segment in bullous pemphigoid.¹⁷³⁹ Male patients are more likely to have antibodies to BP180, whereas antibodies to BP230 occur with equal frequency.¹⁷⁴⁰ A defect in the BP180 gene is the defect in the so-called 'GABEB variant' of junctional epidermolysis bullosa, also known as junctional epidermolysis bullosa, non-Herlitz type (see p. 160). The bullous pemphigoid antigen 1 gene encodes not only epithelial isoforms of this antigen but also variants expressed in the neurons of the central nervous system and in Schwann cells. Bullous pemphigoid may coexist with multiple sclerosis, and it has been suggested that in such cases products of the gene act as shared autoantigens.¹⁶⁸⁰

BP230, a member of the plakin family of proteins and regulated by homeoprotein transcription factors,¹⁷⁴¹ is restricted to the intracellular hemidesmosomal plaque. Autoantibodies to this antigen were originally thought not to be involved in the initiation of the disease.^{1738,1742}

However, their role may have been underestimated because it appears that they may precipitate and perpetuate the disease.¹⁷⁴³ Molecular genetic studies have revealed distinct chromosomal localizations for the two bullous pemphigoid antigens.¹⁷²⁸ The major antigenic epitopes of the 230-kDa protein map within the C-terminal end.¹⁷⁴⁴ In fact, in studies designed to reveal the most appropriate epitope on BP230 for routine detection of serum autoantibodies, recombinant BP230-C3 (which comprises the C-terminal portion) appeared to be the most suitable for diagnosis, using Western blot and ELISA methods.¹⁷⁴⁵ Autoantibodies to this antigen or a complex of this with the 180-kDa antigen are present in up to 80% of patients with bullous pemphigoid, and those to the 180-kDa antigen (BP180) are present in approximately 30% of patients.¹⁷⁴⁶ Approximately 20% of patients have antibodies directed solely to BP180.¹⁷⁴⁶ A commercially available ELISA kit to detect antibodies to the NC16A domain of BP180 has a specificity of 98% and a sensitivity of 89%.^{1747,1748} ELISA tests that detect epitopes in addition to NC16A are more sensitive than kits that detect only NC16A antigen.¹⁷⁴⁹ Approximately 8% of sera from patients with new bullous pemphigoid react only to regions of BP180 *outside* of NC16A.¹⁷⁵⁰ The clinical expression of the disease has been thought to be the same, no matter which antigen is present.¹⁷⁵¹ However, studies have found evidence that antibodies to the 180-kDa antigen (BP180, BPAg2) are more often associated with oral lesions, a disease less responsive to steroids, and poor prognosis.^{1752,1753} Serum levels of autoantibodies to BP180 correlate with disease activity.^{1738,1754,1755} The autoantibodies are of pathogenic relevance.¹⁷⁵⁶ Nevertheless, autoantibodies to BP180 and BP230 can be found in normal healthy subjects, but they do not bind to the NC16A domain.¹⁷⁵⁷ IgG4, IgG1, and IgE are the major immunoglobulins targeting the NC16A domain of BP180 in bullous pemphigoid.^{1758,1759} IgE autoantibodies are directed in approximately 50% of cases against the same NC16A domain that is recognized by IgG class autoantibodies. In other cases, they target domains slightly 'downstream' from NC16A.¹⁷⁶⁰ A particular monoclonal antibody targeting a segment of NC16A (the 395A5 IgE class murine monoclonal antibody) shares functional properties with the active IgE produced by pemphigoid patients and may prove to be useful in further exploring the mechanisms of IgE antibodies in inducing bullous pemphigoid lesions.¹⁷⁶¹ IgA autoantibodies to various antigens have also been found.^{1762,1763} Their presence is not associated with any clinical differences, nor is the presence of antibodies to the C-terminal region of BP180, as found in cicatricial pemphigoid.¹⁷⁶⁴ In rare cases, antibodies have been described to other antigens – 190 kDa,¹⁷⁶⁵ 105 kDa, 120 kDa,¹⁷⁶⁶ 240 and 138 kDa,¹⁷⁶⁷ and 125 kDa¹⁷⁶⁸ – and to plectin,¹⁷⁶⁹ desmoglein 3,¹⁷⁷⁰ and desmoplakin.^{1771,1772} In one patient with bullous pemphigoid, the lesions evolved over time into epidermolysis bullosa acquisita. The patient also developed IgG2 autoantibodies against type VII collagen.¹⁷⁷³ In another case, there were overlap features of both erythema multiforme and bullous pemphigoid, which had a 230-kDa antigen.¹⁷⁷⁴ Antibodies to laminin 332 (epiligrin), as seen in mucous membrane pemphigoid, were seen in addition to anti-BP180 in a patient with typical bullous pemphigoid developing in association with GVHD.¹⁷⁷⁵ It is worth noting that the bullous pemphigoid antigens are distinct from $\alpha_6\beta_4$ integrin, another major antigen localized on the hemidesmosomes.¹⁷⁷⁶ This antigen is usually destroyed in areas of blistering.¹⁷ Following the fixation of antibody to the bullous pemphigoid antigens, complement is activated, leading to the chemotaxis of neutrophils and eosinophils.⁷²⁵ Mast cells, eotaxin, and IL-5 may also be important in the recruitment of eosinophils.¹⁷⁷⁷⁻¹⁷⁷⁹ The neutrophils and eosinophils release proteolytic enzymes that appear to be responsible for the initial stages of blister formation.^{130,1612,1780} Antibodies binding antigenic sites on the intracellular domains of BP180 may also play a role in the blister formation. Whether this results from internalization of immune complexes or epitope spreading remains to be determined.¹⁷⁸¹⁻¹⁷⁸³ Vascular permeability factor is strongly expressed in bullous pemphigoid, leading to increased microvascular permeabil-

ity, followed by papillary edema that, in turn, contributes to the formation of the blister.¹⁷⁸⁴

Experimentally, autoantibodies to BP180 trigger a signal transducing event that leads to the release of IL-6 and IL-8 from cultured human keratinocytes.¹⁷⁸⁵ In another experiment, T-cell lines from patients with bullous pemphigoid reacted with the same epitopes on the BP180 ectodomain as did the autoantibodies,¹⁷⁸⁶ supporting a role for cellular mechanisms in the pathogenesis of bullous pemphigoid.¹⁷⁸⁶⁻¹⁷⁸⁸

B-cell activating factor (BAFF), a member of the TNF superfamily, acts as a potent B-cell growth factor and co-stimulator of immunoglobulin production.¹⁷⁸⁹ Its levels are increased in the serum of patients with bullous pemphigoid but not pemphigus vulgaris. It may play a critical role in triggering activation of autoreactive B cells in bullous pemphigoid.¹⁷⁸⁹

Bullous pemphigoid appears to be a Th2-mediated disease. There are increased numbers of CD4⁺ T cells and eosinophils in the skin.¹⁷⁹⁰ early in the disease. Serum levels of IP-10, MCP-1, and eotaxin are significantly increased in bullous pemphigoid, and the levels increase significantly with disease severity, as determined by the area affected.¹⁷⁹¹

Etiological triggers

Although the pathogenetic mechanisms involved in blister formation are reasonably well understood, what triggers the formation of the antibodies to the hemidesmosome antigens is unknown. Drugs have been incriminated in a few cases, although there is evidence that the antibodies involved in drug-related cases are, in part, different from those found in usual cases of bullous pemphigoid. The implicated drugs include penicillin derivatives,¹⁷⁹²⁻¹⁷⁹⁴ sulfasalazine,¹⁷⁹⁵ ibuprofen,¹⁷⁹⁵ phenacetin,¹⁷⁹⁶ enalapril,^{1797,1798} captopril, lisinopril,¹⁷⁹⁹ gabapentin,¹⁸⁰⁰ novosabin, levobunolol ophthalmic solution,¹⁸⁰¹ tetracoc, influenza, tetanus, and other vaccinations,¹⁸⁰²⁻¹⁸⁰⁶ a homeopathy regimen,¹⁸⁰⁷ nifedipine,^{1808,1809} 5-aminosalicylic acid,¹⁸¹⁰ doxazosin,¹⁸⁰⁸ serratiopeptidase,¹⁸¹¹ losartan,^{1798,1812} cephalixin,¹⁸¹³ bumetanide,¹⁸¹⁴ fluoxetine,¹⁸¹⁵ chloroquine,¹⁸¹⁶ antipsychotic drugs,¹⁸¹⁷ enoxaparin,¹⁸¹⁸ ciprofloxacin,¹⁸¹⁹ furosemide (frusemide),^{1820,1821} neuroleptics,¹⁸²² penicillamine,¹⁸²³ gliptin plus metformin,¹⁸²⁴ intravenous iodine, etanercept,¹⁸²⁵ levofloxacin,¹⁸²⁶ and topical fluorouracil.¹⁷⁹⁶ Influenza vaccination does not appear to be an important trigger for bullous pemphigoid.¹⁸²⁷ Trauma,^{1828,1829} burns,^{1422,1830-1833} lymphedema,¹⁸³⁴ phototherapy,¹⁸³⁵ and radiation¹⁸³⁶⁻¹⁸³⁹ have been implicated in a very small number of cases. Bullous pemphigoid rarely arises in surgical wounds^{1840,1841} or the skin overlying a hemodialysis fistula.^{1842,1843} Herpesvirus has been demonstrated in lesional skin in a few cases. This finding is of doubtful significance.¹⁸⁴⁴

Treatment of bullous pemphigoid

There appears to be inadequate evidence to recommend a specific treatment regimen for this disease.^{1845,1846} Systemic corticosteroids are a mainstay of treatment, but a systematic review found that doses of prednisolone >0.75 mg/kg per day did not provide additional benefit.¹⁸⁴⁵ The addition of plasma exchange or azathioprine to corticosteroids was not established as being beneficial. *Topical* corticosteroids are particularly useful in the elderly and in patients with less than 20% body surface involvement.^{1719,1847} Mycophenolate mofetil and azathioprine have similar efficacy when used as adjuvant therapy with oral methylprednisolone.¹⁸⁴⁸ Alternatives to conventional therapy with corticosteroids, with or without a corticosteroid-sparing agent, include intravenous immunoglobulin, alone or in combination with other immunosuppressive therapies,¹⁸⁴⁹⁻¹⁸⁵¹ methotrexate,¹⁷¹⁵ and the anti-CD20 monoclonal antibody rituximab.^{1665,1852}

Histopathology^{895,1853}

In bullous pemphigoid, there is a unilocular subepidermal blister, with eosinophils being the predominant cell in the dermis and blister cavity (Fig. 6.24). If the biopsy is taken from a bulla on otherwise

Figure 6.24 Bullous pemphigoid. (A) There is a subepidermal blister, the lumen of which contains eosinophils. (B) There are relatively few eosinophils ('cell poor') in the blister. (C) There are numerous eosinophils in the upper dermis at the edge of the blister. (H&E)

Figure 6.25 Vesicular pemphigoid. There is a small subepidermal blister. (H&E)

normal-appearing skin, there is only a sparse dermal infiltrate; bullae with an erythematous base have a much heavier infiltrate of inflammatory cells in the upper dermis. Eosinophilic 'flame figures' are a rare finding.¹⁸⁵⁴ In addition to eosinophils, there are some neutrophils and lymphocytes. Eosinophilic spongiosis may be seen in the clinically erythematous skin bordering the blister.¹⁸⁵⁵

In lesions of several days' duration, the blister may appear intraepidermal in location at its periphery as a result of regeneration. Sometimes epidermal necrosis occurs in the roof of the blister.¹⁸⁵⁶ There are no isolated, necrotic, basal keratinocytes in the roof of early blisters, as sometimes are seen in pemphigoid gestationis.

The variants of bullous pemphigoid (discussed previously) show some distinguishing histological features reflecting their different clinical appearances. In *vesicular pemphigoid*, the lesions are quite small (Fig. 6.25), whereas in *pemphigoid vegetans* there is usually prominent acanthosis of the epidermis. Acanthosis is also present in *pemphigoid nodularis*; in addition, there is overlying hyperkeratosis and mild papillomatosis.

Prodromal lesions of bullous pemphigoid show edema of the papillary dermis and a superficial and mid-dermal perivascular infiltrate with numerous eosinophils, occasional lymphocytes, and rare neutrophils. Interstitial eosinophils may also be present. There are usually more eosinophils than in an arthropod bite reaction. The eosinophils may line up along the basement membrane. A few eosinophils are found within the epidermis (Fig. 6.26). Sometimes there is eosinophilic spongiosis as well.¹⁸⁵⁷ Occasional examples of bullous pemphigoid feature a predominance of neutrophils; these may line up along the basilar layer.¹⁸⁵⁸

'Caterpillar bodies' (segmented, eosinophilic, PAS-positive globules arranged in linear array in the roof of blisters)¹⁸⁵⁹ are a feature of porphyria cutanea tarda. They are sometimes seen in other blistering diseases, including bullous pemphigoid.¹⁸⁵⁹

Cases that commenced with the histological features of erythema multiforme and progressed to bullous pemphigoid have been reported.¹⁸⁶⁰ One such case has already been mentioned.¹⁷⁷⁴ There were no features to suggest paraneoplastic pemphigus. In another case, suprabasal acantholysis preceded the development of bullous pemphigoid.¹⁸⁶¹

The bullous pemphigoid-like lesions that develop in patients with chronic lymphocytic leukemia have a significant Langerhans cell component.¹⁸⁶²

Direct IF almost invariably shows a linear, homogeneous deposition of IgG and/or C3 along the basement membrane zone of the skin

Figure 6.26 Bullous pemphigoid, prodromal stage. (A) There is focal eosinophilic spongiosis, and numerous dermal eosinophils are present. (B), (C) Two other prodromal cases with eosinophils lined up along the basement membrane. (H&E)

around the lesion (Fig. 6.27).^{1863–1866} In early stages of the disease, only C3 may be present. Some commercially available antisera have low levels of antibody to the IgG4 subclass, and this may be responsible for false-negative results obtained with IgG.¹⁸⁶⁷ Incidentally, IgG4 is the predominant subclass of IgG in prodromal lesions.¹⁸⁶⁸ IgM and IgA are present in approximately 20% of cases.¹⁸⁶⁹ Some cases with IgA deposits have oral lesions. One study suggests adding a stain for C1q to the direct IF protocol because 100% of their cases showed positive basement membrane zone staining for IgG, C3, and/or C1q.¹⁸⁷⁰ Laser scanning confocal microscopy can be used to determine the localization of *in vivo*-bound IgG in the basement membrane zone.¹⁸⁷¹ Another technique, FOAM, can be used to increase the sensitivity and resolution capability of conventional immunofluorescence microscopy.¹⁸⁷² Microwave irradiation in urea may be used to retrieve the bullous pemphigoid antigen from paraffin-embedded material.¹⁸⁷³

Circulating anti-basement membrane zone antibodies, usually of IgG class, are present in 60–80% of patients, depending on the substrate used.^{1874–1877} Indirect IF was positive in 96% of patients with bullous pemphigoid in one series, whereas the BP180 NC16A antibody was detected using ELISA in the same percentage of cases.¹⁸⁷⁸

Figure 6.27 Bullous pemphigoid. The basement membrane zone shows a linear pattern of staining for C3. (Direct immunofluorescence)

There is some debate about the relative sensitivity of indirect IF on salt-split skin versus ELISA in the diagnosis of pemphigoid; based on a review of the literature, at least one group has argued that ELISA for BP180 (NC16A) does not have a higher sensitivity than salt-split skin indirect IF.¹⁸⁷⁹ Indirect IF using blister fluid gives similar rates of positivity as sera.^{1880,1881} Their titer does not correlate with disease activity or severity. Antibodies may be absent when circulating immune complexes are formed.¹⁸⁸² Similar antibodies are present in some cases of cicatricial pemphigoid and, rarely, in nonbullous dermatoses. Localization of the target antigen is possible if the substrate is salt-split skin.^{1883,1884} A further method to help localize the anatomical level of the split is staining for type IV collagen; it is present in the base of the blister. Basement membrane zone antibodies have also been detected by indirect IF in the urine of patients with bullous pemphigoid.¹⁸⁸⁵

Electron microscopy^{1558,1777,1886,1887}

In the cell-poor blisters, there is focal thinning and disruption of anchoring filaments with formation of the split in the lamina lucida. In the cell-rich lesions, there is more extensive damage in the basement membrane zone following the migration of eosinophils into this region. There is disintegration of the lamina lucida and fragmentation of anchoring fibrils and hemidesmosomes. The basal cells may show some vacuolization.

Immunoelectron microscopy shows that the immunoreactants are in the lamina lucida and in the vicinity of the cytoplasmic plaque of the basal cell hemidesmosomes.^{1620,1722,1888} Some deposits are located on the intracellular portion of the hemidesmosomes.¹⁸⁸⁹ There are no deposits beneath melanocytes.

Differential diagnosis

At the early stage of eosinophilic spongioid, pemphigoid and *pemphigus vulgaris* can resemble one another, but direct IF allows clear separation of the two, and the acantholytic appearance that defines classic pemphigus is not confused with the subepidermal separation of pemphigoid. Eosinophilic spongioid has been reported in a case of lichen sclerosus, but in that case direct IF was positive for linear IgG and C3, suggesting coexistence with pemphigoid.¹⁸⁵⁷ Reliable differentiation from *cicatricial pemphigoid* with cutaneous involvement, or *pemphigoid gestationis*, may not be possible, and they are widely considered to be closely related disorders (see subsequent discussions). However, cicatricial pemphigoid may actually be a complex of diseases that includes the mucosal variant of linear IgA disease and epidermolysis bullosa acquisita as well as pemphigoid, which may allow differentiation based on direct IF methods (see later). In addition, cicatricial pemphigoid often shows more neutrophils than eosinophils and a greater degree of scarring than ordinary pemphigoid.

A significant differential diagnostic problem can arise in differentiating pemphigoid from epidermolysis bullosa acquisita because there can be overlapping clinical as well as microscopic features (see later). Both conditions can show linear IgG and C3 deposition along the dermal-epidermal junction. However, the target antigens differ in that epidermolysis bullosa acquisita antibody binds to type VII collagen, a component of anchoring fibrils that are found below the lamina densa of the basement membrane zone. In pemphigoid, the target antigen is associated with the hemidesmosome complex, above the lamina densa. Using salt-split skin, the immunoreactants are found on the epidermal side of the preparation in pemphigoid, in contrast to epidermolysis bullosa acquisita in which they are found on the dermal side.^{1890,1891} Uncommonly, deposits are found on the dermal side in bullous pemphigoid, but the reasons for this are unclear.¹⁸⁹²⁻¹⁸⁹⁴ It has been suggested that extracellular epitopes of the 180-kDa antigen are separated from the epidermis during the salt-splitting process.¹⁸⁹⁵ Staining of the dermal side of the separation also occurs in examples of the rare anti-p200 pemphigoid, whose target antigen resides in the lower lamina

lucida of the basement membrane zone (see the following discussion). Saline splitting can be performed either as part of a direct or an indirect IF procedure. We have most often employed this method in direct IF, with very reliable results.

Pemphigoid gestationis shows considerable microscopic overlap with pemphigoid, although there may be pronounced edema of dermal papillae ('teardrop-shaped' papillae). On direct IF, pemphigoid gestationis is more apt than pemphigoid to show only linear C3 deposition along the junctional zone, and indirect IF studies are typically negative unless a 'complement-enhanced' procedure is performed (see later). A major distinction is that pemphigoid is particularly unusual in young adults. In circumstances in which a young woman has clinical, microscopic, and immunofluorescence findings of pemphigoid, inquiry into a history of recent pregnancy should be considered and the possibility of choriocarcinoma also entertained. *Linear IgA disease* can closely resemble pemphigoid microscopically; although on biopsy it shows accumulations of neutrophils in dermal papillae, this change can occasionally be seen in pemphigoid.¹⁸⁵⁸ Elicitation by a drug, such as vancomycin, can often be shown in the former disease, and the positive linear IgA deposition that defines the disease is regularly found on direct IF study. IgA deposition sometimes occurs in pemphigoid, but always with IgG and C3 positivity, and staining for IgA is typically less intense than for those other antibodies. Similarly, papillary neutrophilic microabscesses are a hallmark of *dermatitis herpetiformis*, but direct IF study shows granular IgA deposition (often accompanied by C3 and fibrin) along the basement membrane zone, frequently concentrated at tips of dermal papillae. *Erythema multiforme* has a distinct set of microscopic changes (vacuolar alteration of the basilar layer, apoptotic body formation at all levels of the epidermis, and a mild upper dermal perivascular lymphocytic infiltrate) and shows negative or nonspecific findings on direct IF study. Instances of erythema multiforme evolving into bullous pemphigoid probably occur as a result of epitope spreading. This mechanism may also explain the development of bullous pemphigoid in a patient with suspected non-Herlitz junctional epidermolysis bullosa.¹⁸⁹⁶

Less common differential diagnostic problems can arise when attempting to distinguish pemphigoid vegetans from pemphigus vegetans that lacks acantholysis or pemphigoid nodularis with subtle subepidermal separation from prurigo nodularis. Direct IF studies can be highly useful in these circumstances. There is an example of bullae associated with primary systemic amyloidosis in which the lesions closely resembled pemphigoid (subepidermal separation, an infiltrate containing eosinophils) and demonstrated equivocal staining for amyloid; dermal amyloid fibrils were identified by electron microscopy.¹⁸⁹⁷ 'Caterpillar bodies' are most closely associated with porphyria cutanea tarda; the rare lesion of pemphigoid displaying this change would be expected to lack the vessel wall thickening seen in that disease, to have a dermal infiltrate containing eosinophils, and to display characteristic direct and indirect IF findings.

PEMPHIGOID GESTATIONIS

Pemphigoid gestationis (also known as herpes gestationis) is a rare, pruritic, vesiculobullous dermatosis of pregnancy and the puerperium.¹⁸⁹⁸⁻¹⁹⁰⁶ It occurs in approximately 1 in 50,000 pregnancies and occasionally in association with hydatidiform mole^{1903,1907} or choriocarcinoma.¹⁹⁰⁸ It accounts for less than 5% of the pruritic dermatoses of pregnancy.¹⁹⁰⁹ The onset of the disease is usually in the second or third trimester of pregnancy with the development of papules and urticarial plaques, initially localized to the periumbilical region. Subsequently, the lesions spread to involve the trunk and extremities, becoming vesiculobullous in form.¹⁸⁹⁸ Sometimes the lesions are confined to the legs with no abdominal involvement.¹⁹¹⁰ Mucosal lesions are uncommon.^{1910,1911} Untreated, the lesions persist through the

pregnancy, but they subside within several days or weeks of delivery;^{1912,1913} persistence for many months or years has been reported.^{1914–1918} Oral contraceptives sometimes cause exacerbations.¹⁹¹⁹ Cases with overlap features with bullous pemphigoid have been reported, as has the conversion of pemphigoid gestationis to bullous pemphigoid.^{1920–1922} The diagnosis can be made by the use of a commercially available BP180 NC16A ELISA.¹⁹²³

Pemphigoid gestationis usually recurs in subsequent pregnancies and at an earlier stage.^{1924,1925} ‘Skipped’ pregnancies are more likely to occur following a change in paternity or when the mother and fetus are fully compatible at the HLA-D locus.^{1905,1908,1926} Sometimes there is no explanation for the ‘skipped’ pregnancies.¹⁹²⁷ It has also occurred in a pregnancy initiated by *in vitro* fertilization and intracytoplasmic sperm injection.¹⁹²⁸

Most reports have shown an increased fetal morbidity and mortality related to premature delivery, but in one large study there was no increase in spontaneous abortions or stillbirths.^{1929,1930} In a series of 10 cases from the Mayo Clinic, the fetal and maternal outcomes were good in all cases.¹⁹¹⁰ Only rarely does the infant develop transient vesicular lesions resembling those of the mother.^{1924,1931–1933} This results from transfer to the neonate of maternal anti-BP180 autoantibodies. Lesions in the neonate resolve without treatment far before the pathogenic antibody disappears.¹⁹³⁴

Pemphigoid gestationis has been reported in association with other autoimmune diseases, particularly Graves’ disease.^{1905,1935,1936} It also occurs more frequently in patients with the HLA antigens -DR3 and -DR4.^{1908,1937–1939} This HLA phenotype is thought to confer a state of heightened immune responsiveness.¹⁹⁰⁸ A major initiating event in pemphigoid gestationis is the aberrant expression of the class II molecules of the major histocompatibility complex in the placenta.^{1940,1941} Using sensitive techniques, it has been found that all patients with pemphigoid gestationis possess a circulating autoantibody of IgG1 class (the pemphigoid gestationis factor) that has complement-binding activity.^{1942–1944} This antibody is directed against a placental matrix antigen that cross-reacts with an antigen in the basement membrane of skin.¹⁹⁰⁸ The antigen has been further characterized as a basement zone glycoprotein of 180 kDa which is the same as the bullous pemphigoid antigen (BP180). Epitope mapping analyses have revealed that both bullous pemphigoid and pemphigoid gestationis sera react with one of four (possibly five) epitopes within the noncollagenous (extracellular) domain (NC16A) of BP180.^{1945,1946} The major epitopes targeted have been called MCW-1 and MCW-2. There is no reaction to MCW-4, the site targeted in lichen planus pemphigoides.¹⁹⁴⁵ Some binding of antibody to BP230 may occur.¹⁹⁴⁷ A case has been reported with antibodies to BP180, BP230, and 290-kDa type VII collagen – probably an example of epitope spreading.¹⁹⁴⁸ Antibodies in all IgG subclasses have been found;¹⁹⁴⁵ IgG4 is the predominant subclass.¹⁹⁴⁹ IgA autoantibodies that targeted the C-terminus of BP180 were present in one patient with predominant involvement of oral mucous membrane.¹⁹¹¹ A cytotoxic anti-HLA antibody has also been demonstrated.^{1950,1951} They may develop coincidentally with the anti-basement membrane zone antibodies, reflecting a common immunological event.¹⁹⁵² Activation of complement and the release of toxic cationic proteins from eosinophils have an effector role in the formation of the cutaneous lesions.¹⁹⁵³ Lymphocytes of Th2 type might be implicated in the very early stages of the disease.¹⁹⁵⁴

Systemic corticosteroids are often used to treat this condition. Antihistamines are used as adjuvant therapy to control the itch.¹⁹²⁸ In mild cases, with limited skin involvement, potent topical corticosteroids and antihistamines can be effective.¹⁹⁵⁵ In severe and persistent cases continuing beyond the pregnancy, dapsone or azathioprine have been used as steroid-sparing agents.¹⁹¹⁰ Intravenous immunoglobulin and cyclosporine were used in another case. Long-term remission has also been obtained with rituximab.¹⁹¹⁸ Another persistent case, not responsive to corticosteroids, was successfully treated with minocy-

cline and nicotinamide.¹⁹²⁵ Successful treatment has also been reported with immunoapheresis and immunoabsorption.^{1956,1957}

Histopathology^{1919,1924,1958}

In early urticarial lesions, there is marked edema of the papillary dermis, sometimes producing ‘teardrop-shaped’ papillae (Fig. 6.28), and a superficial and mid-dermal infiltrate of lymphocytes, histiocytes, and eosinophils. The infiltrate is predominantly perivascular in location. Overlying the tips of the dermal papillae there is often focal spongiosis and, sometimes, necrosis of basal keratinocytes. The vesiculobullous lesions that form are subepidermal. They contain eosinophils, lymphocytes, and histiocytes; a similar infiltrate is present in the superficial dermis (Fig. 6.29). The eosinophils usually form microabscesses in the dermal papillae. A small number of neutrophils may also be present.

Direct IF shows C3 and, sometimes, IgG in a linear pattern along the basement membrane zone.^{1924,1959,1960} These immunoreactants are found in the lamina lucida, as in bullous pemphigoid.^{1961,1962} That is, using salt-split skin, the immunoreactants are on the epidermal side. One case with coexisting intercellular IgG deposits has been

Figure 6.28 Pemphigoid gestationis. There is pronounced superficial dermal edema, producing ‘teardrop-shaped’ papillae.

Figure 6.29 Pemphigoid gestationis. There is subepidermal clefting with both neutrophils and eosinophils in the dermal infiltrate. (H&E)

reported.¹⁹⁶³ Eosinophil major basic protein can also be detected in the upper dermis by immunofluorescent techniques.¹⁹⁵³ Circulating anti-basement membrane zone antibodies are uncommon.¹⁹⁶⁴ As mentioned previously, a circulating factor (the pemphigoid gestationis factor), which fixes complement at the dermoepidermal junction of normal human skin, is found in 80% of cases;^{1965,1966} this figure increases to 100% if sensitive techniques are used.¹⁹⁰⁸

Electron microscopy^{1958,1959,1967}

The cleavage occurs at the level of the sub-basal dense plate.¹⁹²⁹ Cleavage through upper hemidesmosomal structures can occur in parallel. Degenerative changes are present in some of the basal cells.¹⁹⁵⁹

Differential diagnosis

The microscopic differential diagnosis in early stages can include either *urticaria* or those conditions characterized by *eosinophilic spongiosis*. Fully developed blisters would be difficult to distinguish from *bullous pemphigoid*. In the presence of papillary neutrophilic and/or eosinophilic microabscesses, consideration would also be given to *epidermolysis bullosa acquisita*, *dermatitis herpetiformis*, *linear IgA disease*, or *bullous lupus erythematosus*. The clinical history, usually that of a young woman who is or has recently been pregnant, would heavily favor pemphigoid gestationis, and immunofluorescent findings would provide strong support. Epidermolysis bullosa acquisita also favors middle-aged to older adults, and an immunofluorescent procedure with salt splitting would show staining of the floor, rather than the roof, of the subepidermal separation. Dermatitis herpetiformis and linear IgA disease would show, respectively, granular or linear basement membrane zone IgA deposits on direct IF. Bullous lupus erythematosus could certainly occur in a young woman and possibly during pregnancy, and both conditions would show linear IgG and/or C3 basement membrane zone deposition. However, the majority of patients with bullous lupus erythematosus have other clinical or serologic evidence of lupus erythematosus, and again, saline splitting in that disease would show positivity along the floor, rather than the roof, of the subepidermal separation. Another major differential diagnostic concern, *pruritic urticarial papules and plaques of pregnancy* (PUPPP), also displays spongiosis, but subepidermal blister formation does not occur and vesicular lesions form intraepidermally. Direct immunofluorescent studies are particularly helpful in this situation because the changes in pruritic urticarial papules and plaques of pregnancy are negative or nonspecific. Eosinophil major basic protein is more abundant in pemphigoid gestationis than in PUPPP (see p. 256).¹⁹⁶⁸

ARTHROPOD BITES

The bite of certain arthropods will result in a bullous lesion in susceptible individuals.¹⁹⁶⁹ There may be a subepidermal blister or a mixed intraepidermal and subepidermal lesion with thin strands of keratinocytes bridging the bulla (Fig. 6.30). Eosinophils are usually present in the blister. The dermal infiltrate consists of lymphocytes and eosinophils around vessels in the superficial and deep dermis; interstitial eosinophils are also present.

DRUG REACTIONS

Certain drugs may produce a vesiculobullous eruption that resembles bullous pemphigoid both clinically and histologically. At other times, the resemblance is less complete. The second-generation quinolones (e.g., ciprofloxacin and lomefloxacin) may produce subepidermal blisters with a mixed cellular infiltrate, including eosinophils.¹⁹⁷⁰ The reaction is often photoexacerbated.

Figure 6.30 Arthropod bite reaction in a sensitized person. Thin columns of surviving keratinocytes produce a characteristic multilocular blister that is both intraepidermal and subepidermal. There are many eosinophils in the inflammatory infiltrate. (H&E)

EPIDERMOLYSIS BULLOSA

Eosinophils have been found in the bullae of all three major subtypes of epidermolysis bullosa, particularly in blisters biopsied in the neonatal period. The presence of eosinophils does not appear to characterize any particular subtype.¹⁰⁴⁵

SUBEPIDERMAL BLISTERS WITH NEUTROPHILS

Neutrophils are a major component of the inflammatory cell infiltrate in the dermis in early lesions of dermatitis herpetiformis and in linear IgA bullous dermatosis, mucous membrane pemphigoid, ocular cicatricial (mucous membrane) pemphigoid, and localized cicatricial pemphigoid. Bullae are an uncommon manifestation of urticaria, acute vasculitis, lupus erythematosus, erysipelas, and Sweet's syndrome. Intraepidermal neutrophilic spongiosis and subepidermal vesicles with neutrophils may be seen in rheumatoid neutrophilic dermatosis.¹⁹⁷¹ Neutrophils are abundant in some inflammatory forms of epidermolysis bullosa acquisita and in the recently described entities of deep lamina lucida (anti-p105) pemphigoid and anti-p200 pemphigoid. A 'superficial neutrophilic dermolysis with subepidermal bulla formation' has been reported in a patient with hepatobiliary disease.¹⁹⁷²

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is a rare, chronic, subepidermal blistering disorder characterized by the presence of intensely pruritic papules and vesicles, granular deposition of IgA in the dermal papillae, and a high incidence of gluten-sensitive enteropathy.¹⁹⁷³⁻¹⁹⁷⁸ Its pathogenesis appears to involve autoantibodies to transglutaminase, but their exact mechanism of action requires further elucidation. The incidence of dermatitis herpetiformis actually appears to be decreasing, at least in some populations, whereas that of celiac disease is increasing. This is likely due to the changing criteria for celiac disease, the relative ease of diagnosing it through screening for antiendomysial and tissue transglutaminase antibodies, and the resulting earlier imposition of a gluten-free diet, as well as a general reduction in gluten consumption.^{1979,1980}

The cutaneous papulovesicles have a characteristic herpetiform grouping and a predilection for extensor surfaces, usually in symmetrical distribution.¹⁹⁷⁴ Sites of involvement include the elbows, the knees, the shoulders, the nape of the neck, the sacral area, and the scalp; mucous membranes are infrequently involved.^{1981–1983} Localization to the face or palms is rare.^{1984,1985} In addition to papulovesicles, excoriations are almost invariably present. Prurigo nodules are extremely rare manifestations of the disease.¹⁹⁸⁶ Bullae are quite uncommon.¹⁹⁷⁴ One case with lesions mimicking prurigo pigmentosa has been reported.¹⁹⁸⁷ Another case presented as a chronic urticaria.¹⁹⁸⁸ Onset of the disease is most frequent in early adult life, but it may occur at any age, including childhood.^{1989,1990} A high prevalence of dermatitis herpetiformis among pediatric patients has been reported in one study.¹⁹⁹¹ There is a male preponderance. In women with the disease, perimenstrual exacerbations sometimes occur.¹⁹⁹² The HLA antigens B8, DR3, DQW2, and DQ8 on chromosome 6 are increased in frequency in those with the disease.^{1993–1996} This haplotype is uncommon in Japanese patients with the disease.¹⁹⁹⁷ In fact, the absence of HLA-DQ2/DQ8, the inability to identify celiac disease in most cases, the relatively high proportion of patients with fibrillar (as opposed to granular) IgA deposition on direct IF, and the unusual distribution of clinical lesions have suggested to some authors that Japanese dermatitis herpetiformis may represent a distinct subset of the disease.¹⁹⁹⁸ The concordance of dermatitis herpetiformis and celiac disease occurs in monozygous twins.¹⁹⁹⁶

A gluten-sensitive enteropathy is present in approximately 90% of cases, although clinical symptoms of this are quite uncommon.¹⁹⁹⁹ A gluten-free diet usually leads to a reversal of the intestinal villous atrophy and improved control of the skin lesions.²⁰⁰⁰ This diet also has a protective effect against the development of lymphoma.^{2001,2002} There is also a high incidence of gluten-sensitive enteropathy in relatives, although very few of the relatives with an enteropathy have dermatitis herpetiformis.²⁰⁰³ In a series of 264 patients from the Mayo Clinic, only 12.6% of patients had established celiac disease. Mucosal changes consistent with gluten-sensitive enteropathy were present in 69.1% of the 55 patients on whom a small bowel biopsy was performed.²⁰⁰⁴ Chronic atrophic gastritis is more frequent in patients with dermatitis herpetiformis than in a control population; this occurs more commonly in the corpus than in the antrum.²⁰⁰⁵

Circulating antibodies to reticulin,²⁰⁰⁶ gliadin,²⁰⁰⁷ nuclear components, human jejunum,²⁰⁰⁸ gastric parietal cells,²⁰⁰⁹ and thyroid antigens²⁰¹⁰ have been reported in variable percentages. Only the presence of IgA-class endomysial antibodies is of diagnostic importance.^{2006,2011–2014} They are present in 70% of patients with dermatitis herpetiformis on a normal diet and in 100% of those with villous atrophy.²⁰¹⁵ The autoantigen of endomysial antibodies in celiac disease is tissue transglutaminase (tTG), an enzyme involved in cross-linking certain intracellular and extracellular molecules.^{2016,2017} Gluten challenge usually converts seronegative cases to seropositive, whereas a gluten-free diet results in a rapid decrease in the titer of various antibodies.^{2015,2018,2019} Demonstration of this antibody to tTG may assist in making a diagnosis of dermatitis herpetiformis when clinical and histological features are equivocal.^{2020,2021}

Dermatitis herpetiformis has been associated sporadically with autoimmune thyroid disease,²⁰²² ulcerative colitis,^{2004,2023–2025} sarcoidosis,²⁰⁰⁴ type 1 diabetes mellitus,²⁰²⁶ SLE,^{2027,2028} rheumatoid arthritis,²⁰²² Sjögren's syndrome,^{2024,2029} Addison's disease,²⁰³⁰ primary biliary cirrhosis,²⁰³¹ lichen planopilaris,^{2032,2033} palmoplantar keratoderma,²⁰³⁴ atopic disorders,^{2035,2036} vitiligo, recurrent tonsillitis,²⁰³⁷ alopecia areata,²⁰²⁴ immune complex nephritis,²⁰³⁸ and psoriasis.²⁰³⁹ Although there are reports of its association with internal cancers, only the development of intestinal lymphomas appears to be of statistical significance.^{1701,2040} Its incidence is very low.^{2002,2004} Cases of concomitant cutaneous T-cell lymphoma have been reported.^{2041,2042}

If untreated, dermatitis herpetiformis has a protracted course, although there may be long periods of remission.^{2043,2044} In one study,

12% of patients went into remission, defined as an absence of signs and symptoms of dermatitis herpetiformis for more than 2 years while not receiving therapy or maintaining a gluten-free diet.²⁰⁴⁵ Individual lesions persist for days to weeks. Iodine and nonsteroidal anti-inflammatory drugs may provoke or exacerbate the disease in susceptible individuals.^{2046–2048} In one case, the disease was precipitated by the administration of a gonadotropin-releasing hormone analogue.²⁰⁴⁹ Two cases of dermatitis herpetiformis precipitated by the use of a commercial cleaning solution have been reported.²⁰⁵⁰ There is evidence for reduced mortality among patients with dermatitis herpetiformis compared to a control population, possibly related in part to dietary and lifestyle factors.²⁰⁵¹

Pathogenesis²⁰⁵²

The pathogenesis of dermatitis herpetiformis involves the binding of IgA antibodies formed in the gut to skin transglutaminases (TGs).^{2043,2053,2054} In skin, at least six TG isoenzymes are present. Initially, studies examined TG2, which is expressed by basal keratinocytes. TG3, like keratinocyte (type 1) TG, appears to be involved in the stabilization of the cornified envelope. It has not been found in the dermis and, accordingly, it was not regarded as a potential target antigen. Furthermore, initial studies showed that the deposits are partly localized to the microfibrillar bundles in the dermal papillae, possibly to fibrillin-reactive fibrils.²⁰⁵⁵ Other studies have shown a haphazard distribution of the deposits.^{2056,2057} A recent study localized the deposits to the small blood vessels in the papillary dermis.²⁰⁵⁸ The deposits contained IgA/TG3 aggregates, possibly representing immune complexes.²⁰⁵⁸ Similar deposits have been found in the healthy skin of patients with celiac disease, raising questions about their pathogenic significance.²⁰⁵⁹ It is too early to state that TG3 is the major autoantigen in dermatitis herpetiformis.²⁰⁶⁰ The IgA deposited in the skin was originally thought to be of A₁ class only,²⁰⁶¹ but IgA₂ has also been detected in these deposits.²⁰⁶² Recent experimental studies using human skin-grafted mice suggest that IgA-anti-TG3 antibodies are directly responsible for the immune deposits in dermatitis herpetiformis and that the TG3 is derived from human epidermis.²⁰⁶³ Whatever the mechanism involved in the formation and deposition of IgA deposits, it appears that the final common pathway involves activation of the complement system followed by chemotaxis of neutrophils into the papillary dermis.²⁰⁵⁴ Partial IgA deficiency has been seen in several patients with dermatitis herpetiformis. The patients had sufficient IgA to form endomysial and tissue transglutaminase antibodies.²⁰⁶⁴ Cytokines such as endothelial leukocyte adhesion molecule (ELAM), IL-8, and granulocyte-macrophage colony-stimulating factor (GM-CSF) also contribute to the infiltration and activation of neutrophils.^{2065,2066} The elevated serum levels of IL-8 originate from the small bowel as a mucosal immune response to gluten ingestion.²⁰⁶⁷ IL-8 increases the expression of CD11b on the cell surface of neutrophils, influencing neutrophil function.^{2067,2068} Enzymes released from these neutrophils alter or destroy at least two basement membrane components (laminin and type IV collagen), contributing to the formation of blisters.²⁰⁶⁹

Although most studies have focused on the role of immune complexes in the pathogenesis of dermatitis herpetiformis, it appears that activated T cells may also be involved.²⁰⁷⁰ Most of the T cells are CD45RO-positive memory cells,²⁰⁷⁰ they do not bear the γ/δ receptor.²⁰⁷¹ Studies suggest that cytokines from CD4⁺ lymphocytes of the Th2 subtype play an important role in the pathogenesis of dermatitis herpetiformis.^{2066,2072}

A lifelong gluten-free diet is the treatment of choice for dermatitis herpetiformis. It can be a challenging experience, particularly for children.^{1988,2073,2074} The majority of patients clear their lesions within 1–6 months of the commencement of the diet. Dapsone may also be used; it usually clears the lesions quickly. Because all patients develop a

dose-related methemoglobinemia from dapsone, its usage must be curtailed. In patients who cannot tolerate dapsone, alternatives are required. Sulfasalazine has been effective in the small number of cases reported.²⁰⁷⁵ If a gluten challenge is made, then the majority of cases relapse within 2 months.²⁰⁷⁴ Occult sources of gluten must be kept in mind, such as some multivitamin preparations.²⁰⁷⁶

Histopathology¹⁹⁷⁴

Early lesions are characterized by collections of neutrophils and a varying number of eosinophils at the tips of edematous dermal papillae, resulting in the so-called 'papillary microabscesses' (Fig. 6.31). Fibrin is also present near the tips of the dermal papillae, imparting a 'necrotic' appearance. An occasional acantholytic basal cell may also be found above the tips of the papillae.

In lesions of 36–48 hours' duration, the number of eosinophils in the infiltrate is proportionately increased. Some fragmentation of neutrophils is also present. Very occasionally, intraepidermal collections of neutrophils appear to be present; such cases require distinction from the very rare condition known as IgA pemphigus.

In older lesions, subepidermal vesiculation occurs, although initially the interpapillary ridges remain attached, leading to multilocularity of the vesicle:²⁰⁷⁷ after a few days, the attachments break down with the formation of a unilocular blister. The vesicles contain fibrin, neutrophils, eosinophils, and very occasional 'shadow' epidermal cells.²⁰⁰⁹ Aggregates of nuclear dust are sometimes present in the stratum corneum in the old (resolving) lesions.²⁰⁷⁸

Blood vessels in the upper and mid dermis are surrounded by an infiltrate of lymphocytes and histiocytes with a variable admixture of neutrophils and eosinophils. Flame figures mimicking an arthropod bite reaction were present in one case.²⁰⁷⁹ A vasculitis is rarely present but can occasionally be the presenting microscopic finding.²⁰⁸⁰ The editor has also seen an example that first presented as an eosinophilic vasculitis. In urticarial lesions, there is also marked edema of the upper dermis. Neutrophils may not be prominent in such lesions.

Warren and Cockerell reviewed 24 cases of dermatitis herpetiformis and found that 9 of these cases had nonspecific findings on H&E.²⁰⁸¹ These nonspecific cases showed a lymphocytic infiltrate, which was predominantly perivascular with minimal extension into the dermal papillae. In 6 of these cases, there was also fibrosis and ectatic vessels in the dermal papillae. Only 2 of these nonspecific cases had occasional neutrophils.²⁰⁸¹ Others have also reported nonspecific microscopic findings in patients who later proved to have dermatitis herpetiformis;²⁰⁸² in two recent cases, both of which showed changes of lichen simplex chronicus or prurigo nodularis on biopsy, diagnosis was confirmed by serologic studies and by rapid response of skin lesions to dapsone.²⁰⁸³

Direct IF shows granular deposits of IgA in the dermal papillae of perilesional and uninvolved skin, although the deposition is not uniform (Fig. 6.32).^{2084,2085} The deposition is greatest in normal skin adjacent to an active lesion.²⁰⁸⁶ A fibrillar pattern is sometimes recognized.^{1998,2087} Interestingly, IgA is not found in the skin in celiac disease without skin lesions.²⁰⁸⁸ Experience has shown that if IgA is not detected, the disorder usually turns out to be a dermatosis other than dermatitis herpetiformis,²⁰⁸⁹ although rarely IgA is found on a second biopsy when it was not demonstrated on the initial examination.²⁰⁹⁰ In another case that proved to be dermatitis herpetiformis, granular C3 basement membrane zone deposition was identified in the absence of IgA.²⁰⁸³ In a large series from the Mayo Clinic, direct IF testing was positive in 92.4% of the patients tested.²⁰⁰⁴ In a small number of cases with negative direct IF, antibodies to tTG will be present; such cases respond to a gluten-free diet.^{2083,2091} Cases with negative direct IF but with other clinical and laboratory features of dermatitis herpetiformis, including rapid response to dapsone, continue to be reported.^{2092,2093} An immunohistochemical technique using the avidin–biotin–peroxidase complex and paraffin-embedded material has been found to be as effective as

Figure 6.31 Dermatitis herpetiformis. (A) There is a subepidermal blister. (B) A microabscess is present in a dermal papilla. (C) A later lesion with acanthosis and some eosinophils as well as neutrophils in the papillary dermis. (H&E)

Figure 6.32 Dermatitis herpetiformis. There are granular deposits of IgA in the dermal papillae. (Direct immunofluorescence)

direct IF in detecting IgA.²⁰⁹⁴ Other immunoglobulins, particularly IgM, are present in almost 30% of all cases, whereas C3 is found in approximately 50%.^{844,2090} Most studies have recorded a diminution in the quantity of IgA and in the incidence of C3 deposition in patients on a gluten-free diet.²⁰⁹⁵

A study that examined the effects of long-term storage of direct immunofluorescent staining slides at room temperature found that IgA and C3 were the first deposits to fade. A diagnosis is still possible on slides stored in this way for 11 months.²⁰⁹⁶ Mounting media containing an antifading reagent allows storage for 2 years at room temperature.²⁰⁹⁶

The exact nosological position of cases with a granular linear pattern of IgA is uncertain,¹⁹⁷⁴ but they are best regarded as a subgroup of dermatitis herpetiformis.¹⁹⁷⁵

Electron microscopy

Many early studies suggested that the blister formation occurred below the lamina lucida, corresponding to the site of the neutrophilic infiltrate. A recent study demonstrated the split within the lamina lucida.²⁰⁹⁷

Immunoelectron microscopy confirms that the IgA is present in clumps in the dermal papillae. Initially, the IgA was thought to be associated with microfibrillar bundles,²⁰⁹⁸ but recent studies have shown a somewhat haphazard deposition that only sometimes involves the microfibrillar bundles.^{2056,2057}

Differential diagnosis

The histological distinction between dermatitis herpetiformis and linear IgA disease is almost impossible,²⁰⁹⁹ although subtle distinguishing features have been reported (see p. 180).^{2079,2100} Older lesions of dermatitis herpetiformis may resemble bullous pemphigoid, although eosinophils are usually more prominent in the latter condition.²⁰⁷⁹ Rare cases with overlap features between dermatitis herpetiformis and other bullous diseases, including bullous pemphigoid, have been reported.^{2101–2104} This is thought to be due to epitope spreading.²¹⁰⁵ It should be remembered that dermal papillary microabscesses can be seen not only in dermatitis herpetiformis but also in cicatricial pemphigoid, localized cicatricial pemphigoid, bullous lupus erythematosus, linear IgA bullous dermatosis, deep lamina lucida pemphigoid, and, rarely, conventional bullous pemphigoid. Papillary microabscesses also form in pemphigoid gestationis, but they are composed of eosinophils in most cases. Neutrophils are also found in some cases of epidermolysis bullosa acquisita. Distinction among these disorders depends largely on direct IF studies. The only one of these disorders that might create

confusion on immunofluorescence study is bullous lupus erythematosus with granular IgA deposition along the junctional zone. However, other immunoglobulins of at least equal or greater intensity would also be present. In situations in which dermatitis herpetiformis lesions show IgM deposition in addition to IgA, differentiation might require a search for antigliadin, antiendomysial, or anti-transglutaminase antibodies.²¹⁰⁶ Other conditions that feature neutrophils in the dermis can occasionally show accumulation of these cells in the dermal papillae and therefore resemble dermatitis herpetiformis to a degree. A common example is florid leukocytoclastic vasculitis. In this example, unequivocal vasculitis is identified, and direct IF study will show granular deposition of immunoglobulins and complement around vessels; the junctional zone is typically spared, with the possible exception of some granular C3 or fibrin deposition.

LINEAR IgA BULLOUS DERMATOSIS

Linear IgA bullous dermatosis (linear IgA disease) is a rare, sulfone-responsive, subepidermal blistering disorder of unknown etiology in which smooth linear deposits of IgA are found in the basement membrane zone.^{1975,2107–2111} Its incidence has varied in different studies from 0.22 to 2.3 cases per 1 million population per year.²¹¹² It is relatively more common in areas of Africa than in Europe.²¹¹³ There are two clinical variants – chronic bullous dermatosis of childhood and adult linear IgA bullous dermatosis. They are now regarded as different expressions of the same disease²¹¹⁴ because both variants share the same target antigen (a 97- or 285-kDa antigen in the upper lamina lucida).

Chronic bullous dermatosis of childhood

Chronic bullous dermatosis of childhood – known in the past as juvenile dermatitis herpetiformis,²¹¹⁵ juvenile pemphigoid,²¹¹⁶ and linear IgA disease of childhood – is characterized by the abrupt onset, in the first decade of life, of large, tense bullae on a normal or erythematous base.^{2108,2117–2120} They have a predilection for the perioral and genital regions, as well as the lower part of the abdomen and the thighs.²¹²¹ Often, there is a polycyclic grouping, the so-called ‘cluster of jewels’ sign.²¹⁰⁸ Depigmentation is sometimes present.²¹²² Childhood associations with type I diabetes mellitus²¹²³ and trimethoprim-sulfamethoxazole²¹²⁴ have been described. The disease usually runs a benign course, with remission after several months or years.^{2125,2126} In one series, 12% of the cases persisted beyond puberty.²¹⁰⁸ HLA-B8 positivity is associated with a good prognosis.²¹²⁷ The entity known as childhood cicatricial pemphigoid appears to be a variant of chronic bullous dermatosis of childhood and is characterized by severe scarring lesions of mucosae, particularly the conjunctiva.^{2108,2128}

Adult linear IgA bullous dermatosis

Adult linear IgA bullous dermatosis was originally regarded as a subgroup of dermatitis herpetiformis, but it is now known to differ from dermatitis herpetiformis by the absence of gluten-sensitive enteropathy^{2129,2130} and IgA antiendomysial antibodies,^{2012,2013} although antigliadin antibodies are sometimes present.²⁰⁰⁷ Adult linear IgA bullous dermatosis has a heterogeneous clinical presentation that may clinically resemble dermatitis herpetiformis, bullous pemphigoid, forms of prurigo,²¹³¹ toxic epidermal necrolysis,^{2132–2135} or other bullous disorders.^{1650,2136–2141} Sometimes the lesions have an annular configuration²¹⁴² that may resemble erythema annulare centrifugum.^{2142,2143} A rare morbilliform variant due to vancomycin has been reported.^{2144,2145} Bullae usually involve the trunk and limbs; facial and perineal lesions are not as frequent as in the childhood form.²¹⁰⁷ Rarely, the lesions are limited to seborrheic areas.²¹⁴⁶ An association with sarcoidosis,²¹⁴⁷ psoriasis,^{2148,2149} ulcerative colitis,^{2150,2151} Crohn’s disease,^{2152–2154} lymphocytic

colitis,²¹⁵⁵ sclerosing cholangitis,²¹⁵⁶ rheumatoid arthritis,²¹⁵⁷ Castleman's disease,²¹⁵⁸ lymphoma,^{2159,2160} chronic lymphocytic leukemia,²¹⁶¹ other malignant tumors,^{2162–2167} an IgG monoclonal gammopathy,^{2168,2169} autoimmune lymphoproliferative syndrome,²¹⁷⁰ allogeneic bone marrow transplantation,²¹⁷¹ autologous hematopoietic stem cell transplantation,²¹⁷² immune complex glomerulonephritis,^{2173,2174} chronic renal failure^{2175,2176} and α -thalassemia trait,²¹⁷⁷ and Sjögren's syndrome²¹⁷⁸ has been reported. An association with IgA nephropathy has been described on several occasions.²¹⁷⁹ The disease has also followed the therapeutic use of acetaminophen (paracetamol),²¹⁸⁰ captopril,²¹⁸¹ somatostatin,²¹⁸² atorvastatin,²¹⁸³ furosemide (frusemide),²¹⁸⁴ glibenclamide,²¹⁸⁵ penicillin,²¹⁸⁶ amoxicillin,²¹⁸⁶ ampicillin/sulbactam,²¹⁸⁷ cefamandole,²¹⁸⁸ ceftriaxone and metronidazole,²¹⁸⁹ trimethoprim-sulfamethoxazole,²¹⁸² lithium carbonate,²¹⁹⁰ amiodarone,^{2191,2192} phenytoin,^{2182,2193–2195} carbamazepine,²¹⁹⁶ vancomycin,^{2197–2203} ustekinumab in a patient with psoriasis,²²⁰⁴ donepezil,²²⁰⁵ human papillomavirus vaccination,²²⁰⁶ cefuroxime (upon discontinuation),²²⁰⁷ nonsteroidal anti-inflammatory drugs^{2107,2208} such as piroxicam,²²⁰⁹ naproxen, and diclofenac,²²¹⁰ and amlodipine.²²¹¹ Localized disease has followed UV-light treatment of herpes zoster.²²¹² Intense skin exposure is a rare cause of generalized disease.²²¹³ Contact with sodium hypochlorite and a burn from boiling methyl alcohol have also been incriminated.^{2214,2215} The onset of the drug-related cases is usually within 4–14 days of the administration of the implicated drug.²¹⁸² The eruption is self-limited and heals within several weeks of the cessation of the drug. In contrast, the usual adult case runs a chronic course and lesions may persist indefinitely.^{2107,2216,2217} An improvement often occurs during pregnancy, although a relapse is frequent at approximately 3 months postpartum.²²¹⁸ The childhood form often has remissions, and complete clearing sometimes occurs.

In both the adult and the childhood forms, the lesions may be pruritic or burning.²¹⁰⁷ Hemorrhagic bullae may form.²¹¹⁸ Prurigo-like lesions have been reported.^{2219,2220} Mucosal involvement occurs in 80% or more of adults but less frequently in children.^{2221–2223} Pharyngeal and esophageal involvement have been reported.²²²⁴ Scarring conjunctival lesions sometimes develop.^{2222,2225} Cases limited to the eyes are rare.²²²⁶ Such cases may represent IgA variants of cicatricial pemphigoid.^{2227,2228} Other findings have included severe arthralgia²¹¹⁴ and the presence of organ-specific antibodies and of various histocompatibility antigens (Cw7 and DR3), some of which differ from those found in dermatitis herpetiformis.^{1994,2229} However, the incidence of HLA-B8 is increased in both dermatitis herpetiformis and chronic bullous dermatosis of childhood and marginally so in the adult form of the latter.²¹⁰⁷

Pathogenesis

Linear IgA bullous dermatosis is a heterogeneous disease with regard to the localization of target antigens and antibody deposition.^{1302,2230–2236} Target antigens are not restricted to any single component or region of the basement membrane zone.²²³⁷ Epitope spreading is common.²²³⁷ The antigen for the major type (the lamina lucida type) was originally reported to be a 97-kDa protein (laminin, LABD97) or a 120-kDa protein (LAD-1).^{2238,2239} It is now known that these proteins are degradation products of the 180-kDa bullous pemphigoid antigen (BP180, BPAg2). BP180 has a pivotal role in linear IgA disease.²²⁴⁰ It has been suggested that the target antigen involves epitopes in the NC16A domain of BP180, but this appears to be so in only 20% of cases.^{2241,2242} The target in other cases is in the adjacent 15th collagenous domain.^{2243–2248} In 10–25% of cases, the IgA autoantibodies are to antigens in the lamina densa; the antigen in many instances is not known.²²⁴⁹ In some cases, the antigen is type VII collagen, specifically the NC1 domain, the immunodominant epitope for epidermolysis bullosa acquisita.²²⁵⁰ It has been suggested that these cases be called IgA epidermolysis bullosa acquisita.²²⁵¹ Another dermal antigen, LAD285, is a target antigen in up to 35% of cases.²²⁵² Other target antigens have included 100- and 145-kDa proteins²²⁵³ and also 200- and 280-kDa

hemidesmosomal proteins distinct from any known target antigen in this region.^{2254,2255} Childhood cases with IgA antibodies against BP180 or BP230 have been reported.^{1766,2256} The target antigen in drug-induced forms is also heterogeneous.^{2185,2257} In vancomycin-induced disease, the autoantibodies target both BP180 and LAD285.²²⁵⁸ Drug-induced cases are sometimes dermal-binding with the target antigen on the dermal side of salt-split skin.²²⁵⁹ Studies using indirect IF on salt-split skin have usually localized the target antigen to the upper lamina lucida, whereas studies using immunoelectron microscopy have shown a number of cases with deposits in the sublamina densa region of the dermis.²²³² In one series of 46 cases, only 4 had sublamina densa deposits.²²³¹ In a recent study of 101 patients with linear IgA disease, 17 had dermal binding autoantibodies.²²⁵⁹ There were no other features that distinguished these 17 patients from the remainder. Collagen VII, the target antigen in EBA, was the identified antigen in only 2 of the dermal cases, but none of the classic clinical features of EBA were observed in these 2 cases.²²⁵⁹ Circulating IgA antibodies are found in approximately 70% of childhood cases but in only 20% of adult cases.²¹⁰⁷ A higher yield is obtained using split skin as the substrate.²²⁶⁰ These antibodies are thought to have some pathogenetic significance despite their low incidence in the adult forms of the disease. In a small number of cases, circulating IgG antibodies are present as well.^{2261,2262} Such cases have been called *linear IgA/IgG bullous dermatosis* (LAGBD). The antibodies appear to target the ectodomain of BP180.^{2263,2264} The clinical appearance and the histology of these cases resemble linear IgA bullous dermatosis.^{2265–2267}

It appears that in both idiopathic and drug-induced cases, cytokines produced by CD4⁺ lymphocytes, enzymes released by neutrophils and eosinophils, and IgA deposits in the basement membrane zone all contribute to the specific tissue lesions.^{2189,2268}

Dapsone is the treatment of choice for this disease.²²⁶⁹ It may be used alone or in combination with corticosteroids.^{2112,2171} Tacrolimus ointment²²⁷⁰ and intravenous immunoglobulin²¹⁴³ have been used as adjunctive therapy. Other drugs and treatment approaches have included erythromycin,²²⁷¹ flucloxacillin,²²⁷² colchicine,²²⁷³ mycophenolate mofetil, trimethoprim-sulfamethoxazole,²²⁷⁴ thalidomide,²²⁷⁵ and immunoadsorption.²²⁷⁶

Histopathology

Linear IgA bullous dermatosis is a subepidermal blistering disease in which neutrophils are usually the predominant cell in the infiltrate (Fig. 6.33). Accordingly, many cases are indistinguishable on light

Figure 6.33 Linear IgA bullous dermatosis. There is a subepidermal blister with neutrophils in the lumen and in the base. (H&E)

microscopy from dermatitis herpetiformis, with the presence of dermal papillary microabscesses.²¹³⁸ Some adult cases may mimic bullous pemphigoid by having a predominance of eosinophils in the infiltrate.²¹⁰⁷ No attempt has been made to ascertain whether the type of the predominant cell in the infiltrate is merely a reflection of the age of the lesion. Eosinophils are sometimes the predominant cell in the drug-precipitated cases.^{2182,2198,2277} A scanty infiltrate of lymphocytes usually surrounds the small vessels in the superficial plexus.

Attempts have been made to establish criteria for the distinction of linear IgA bullous dermatosis from dermatitis herpetiformis.^{2077,2100} Fibrin is present at the tips of the dermal papillae with underlying leukocytoclasia in nearly all cases of dermatitis herpetiformis.²⁰⁷⁷ However, these changes are also present in three-fourths of the cases of linear IgA disease.²⁰⁷⁷ Furthermore, the neutrophil infiltration in this latter condition tends to be more widespread than that in dermatitis herpetiformis, in which there is relative sparing of the rete tips between each dermal papilla (Fig. 6.34).²¹⁰⁰ In most cases, it is impossible to distinguish between the two conditions.

Direct IF reveals a homogeneous linear pattern of IgA deposition along the basement membrane zone of nonlesional skin (Fig. 6.35).²⁰¹³ This is the only immunoreactant in nearly 80% of cases.²¹⁰⁷ In the

remainder, IgG, IgM, and/or C3 may be present (discussed previously).^{2107,2278,2279} It was initially thought that the IgA was exclusively IgA₁, but IgA₂ may be involved in some cases.²²⁸⁰⁻²²⁸² Based on two cases, it has been suggested that lesions on the volar surface of the forearm may not contain immunoreactants even though they are present in lesions from other body sites.²²⁸³ Until this is clarified, this site should probably be avoided at biopsy. As previously mentioned, circulating IgA antibodies are found more often in childhood than in adult cases. The deposition of IgA in a linear manner along the basement membrane is not specific for linear IgA bullous dermatosis because it may also be found in several bullous dermatoses and cutaneous diseases.²²⁸⁴ Incidentally, IgA is deposited along the basement membrane of the eccrine secretory coils in patients with alcoholic liver disease.²²⁸⁵

Electron microscopy

Most of the ultrastructural studies have been directed at ascertaining the site of deposition of the IgA rather than the anatomical level of the split within the basement membrane zone.²²⁸⁶ In some studies, the split has been within the lamina lucida,^{2286,2287} whereas in others it has been below the basal lamina, as in dermatitis herpetiformis.²²⁸⁸ Most immunoelectron microscopical studies have shown that the deposits are below the lamina densa, as in epidermolysis bullosa acquisita,^{2289,2290} or on either side of the lamina densa in a mirror-image pattern.²²⁹¹ A few studies, involving small numbers of cases, have demonstrated deposits within the lamina lucida.^{2190,2292} In contrast, split-skin studies have shown that the IgA is deposited at a higher level in the basement membrane zone. These conflicting results have already been discussed. They are a reflection of the heterogeneous nature of the condition.

Differential diagnosis

Despite the previously stated microscopic resemblance to other immunobullous diseases, particularly dermatitis herpetiformis, the direct IF findings in linear IgA disease are quite striking and almost always diagnostic. In a minority of cases of linear IgA disease, linear deposition of other immunoglobulins is seen in addition to IgA. This can create confusion with examples of bullous lupus erythematosus, bullous pemphigoid, or cicatricial pemphigoid that include IgA among other immunoglobulins showing linear basement membrane zone deposits. Salt splitting on direct IF may not provide additional help in this regard because, given the heterogeneous nature of this disease, staining may be found either above or below the lamina densa. Typically in linear

Figure 6.34 (A) Linear IgA bullous dermatosis. (B) Neutrophils are present in the upper dermis with some accentuation in the poorly formed dermal papillae. (H&E)

Figure 6.35 Linear IgA bullous dermatosis. There is linear deposition of IgA along the basement membrane. (Direct immunofluorescence)

IgA disease, IgA staining is stronger than for other immunoglobulins, whereas the reverse is the case in other immunobullous diseases. However, as an example of the complexity of this problem, several papers have described cases resembling linear IgA disease with sublamina densa staining variably targeting the 290-kDa type VII collagen antigen of EBA or the 200-kDa lamin γ_1 antigen of p-200 pemphigoid.^{1413,2293} It is evident that, in some cases, correlation with other clinical and laboratory findings may be necessary in order to reach a specific diagnosis.

MUCOUS MEMBRANE PEMPHIGOID

Mucous membrane pemphigoid, formerly referred to as cicatricial pemphigoid, is an uncommon, chronic, autoimmune vesiculobullous disease that is distinguished clinically by its predilection for oral and ocular mucous membranes and a tendency for the lesions to scar.²²⁹⁴⁻²²⁹⁹ There is considerable heterogeneity in terms of age at presentation and the clinical pattern of disease.²³⁰⁰ It occurs predominantly in older age groups, but there are several reports of the disease in children and adolescents.^{2301,2302} There is a female predominance.²²⁹⁵

The mouth is the most frequent site of onset and is eventually involved in 85% of cases.²³⁰³ There are erosions, irregular ulcers, and vesiculobullous lesions. Ocular involvement is also common,²³⁰⁴ and corneal and conjunctival scarring may lead to blindness.^{2225,2295} Some of these cases may represent ocular cicatricial pemphigoid, a unique disease in which there is an IgA antibody that binds to a 45-kDa basement membrane antigen. Mucous membrane involvement is sometimes absent, even in the antiepiligrin variant (see later).^{2305,2306} In mucous membrane pemphigoid, skin lesions occur in approximately 25% of cases, but in only 10% is the skin the initial site of involvement.^{2294,2307} There may be scattered tense bullae that heal without scarring or several areas of erythema with blisters that often heal with scarring.⁷⁰ There is a tendency for blisters to recur in the same area. Generalized cutaneous lesions resembling bullous pemphigoid are uncommon.²³⁰⁸ A vegetans variant of mucous membrane pemphigoid has been reported.²³⁰⁹ The face, neck, upper trunk, scalp, and, to a lesser extent, the axillae and distal parts of the limbs are the usual sites of cutaneous lesions.^{2294,2310,2311} The external genitalia,^{2312,2313} larynx,²³¹⁴⁻²³¹⁷ pharynx, anus, esophagus,²³¹⁸ middle ear,²³¹⁹ and nail plates²³²⁰ may also be involved.²²⁹⁵ Childhood mucous membrane pemphigoid is sometimes confined to the vulva,²³²¹⁻²³²³ a case has been reported of a 20-month-old boy with involvement of the oral and nasal cavities and conjunctivae.²³²⁴ Coexistence with thymoma,²³²⁵ angioimmunoblastic T-cell lymphoma,²³²⁶ carcinoma of the pancreas,²³²⁷ stomach,²³²⁸ lung,^{1502,2329} prostate,²³³⁰ and ovary,²³³¹ celiac disease,²³³² acquired hemophilia,²³³³ and with axial spondyloarthritis,²³³⁴ rheumatoid arthritis,^{2335,2336} SLE,²³³⁷ and other autoimmune diseases,²³³⁸ as well as an association with the ingestion of prazosin,²³³⁹ clonidine,²³⁴⁰ and atenolol,²³⁴¹ have also been reported. Generalization of the disease has followed the use of azathioprine therapy.²³⁴² It may be complicated by the development of herpes simplex infection.²³⁴³ The antiepiligrin variant (AECp; discussed later) appears to be associated with mucosal-predominant disease and an increased relative risk for cancer.^{2344,2345} Patients with ocular cicatricial pemphigoid and/or mucous membrane pemphigoid with antibodies to β_4 integrin have a lower risk of cancer than controls and also a better prognosis.²³⁴⁶

The relationship of mucous membrane pemphigoid to several other subepidermal bullous diseases has been a matter for discussion and some controversy.²³⁴⁷⁻²³⁵¹ This controversy is now largely resolved.

Pathogenesis

Mucous membrane pemphigoid is a heterogeneous group of diseases that share the same clinical phenotype.²³⁵² There are multiple target

antigens that include BP180, BP230, β_4 integrin, laminin 5, uncein, and type VII collagen.²³⁵³ Most patients have autoantibodies that target multiple sites on the extracellular, C-terminus, or intracellular domains of BP180, whereas in bullous pemphigoid and pemphigoid gestationis (herpes gestationis) sera target the NC16A domain.^{1764,2354,2355} These antibodies belong to the IgG (75%) class and/or the IgA (51%) class.²³⁰⁰ They may also target the soluble ectodomains of BP180, including LAD-1 and LABD97 antigens.²³⁵⁶ BP230 and β_4 integrin are the next most commonly targeted antigens.^{2300,2357} A further group, accounting for 2–10% of cases, has IgG autoantibodies directed against epiligrin.^{912,913,2358-2364} Epiligrin is also known as laminin 5, a heterotrimeric ($\alpha_3\beta_3\gamma_2$) adhesion molecule that is a component of the anchoring filaments. Virtually all patients have pathogenic antibodies that bind the α_3 subunit (laminin 332), but there have been occasional cases in which the antibodies have been directed against the β_3 and γ_2 subunits of laminin 5.^{2316,2365-2368} The diagnosis of AECp can be made by the detection of autoantibodies to laminin 332. The ELISA method appears to be specific despite an earlier report finding positivity in some cases of bullous pemphigoid.²³⁶⁹ An immunoprecipitation method was used prior to the introduction of the ELISA test.²³⁷⁰ Interestingly, a deficiency of laminin 5 is present in the lethal (Herlitz) junctional form of epidermolysis bullosa and several other rare forms of the disease (see p. 158). In one case of AECp, there was an underlying gastric carcinoma producing laminin 5.²³⁷¹ Antibodies to laminin 6 are sometimes found.^{2372,2373} The exact contribution of the various autoantibodies to the development of specific disease phenotypes is currently unclear.²³⁰⁰ It has even been claimed that antibodies to BP180 and BP230 may be a secondary phenomenon and not directly related to the pathogenesis.²³⁴⁶ This seems unlikely because disease severity does relate to the presence of these antibodies; a more severe clinical phenotype is associated with predominantly IgA reactivity to multiple BP180 antigens.²³⁰⁰ More than 85% of patients with reactivity to β_4 integrin have ocular involvement.²³⁰⁰ IgG4 autoantibodies were found to predominate in one study of AECp.²³⁷⁴ Several cases of mucous membrane pemphigoid have had autoantibodies directed against a 230- to 240-kDa antigen, a 45-kDa antigen or a 168-kDa mucosal antigen or antigens that could not be characterized.²³⁷⁵⁻²³⁷⁸ Finally, the existence of a rare, scarring, bullous eruption with linear IgA at the dermoepidermal junction raises the question of the relationship of these cases to cicatricial pemphigoid and linear IgA bullous dermatosis.^{2128,2379-2383} In one case,²³⁸² the IgA antibody bound a distinct set of antigens (180 and 130 kDa), quite different from those in any other bullous disease.

Although there is no association between particular HLA class II alleles and autoantibody reactivity to BP230 and β_4 integrin, there is with LAD-1 and dual BP180/LAD-1, particularly DQB1*0301, DRB1*04, and DRB1*11.^{2300,2384,2385}

A few patients with this disease have NC16A domain-specific T cells in their blood.²³⁸⁶ They have also been found in some patients with bullous pemphigoid. TNF- α has been implicated in the pathogenesis.

A systematic review in 2002 concluded that there is poor evidence from the literature that systemic corticosteroids are the best treatment, even though they have been regarded as the gold standard. Intravenous immunoglobulin,^{2356,2387} mycophenolate mofetil,²³⁸⁸ thalidomide,²³⁸⁹ dexamethasone-cyclophosphamide pulse therapy,²³⁵⁷ etanercept, and infliximab²³⁹⁰ have all been used to treat mucous membrane pemphigoid. Rituximab has been of benefit in some cases, although there are occasional treatment failures or relapses, and its influence on the long-term clinical course of the disease is currently unclear.²³⁹¹

Histopathology

In mucous membrane pemphigoid, there is a subepidermal blister that shows a variable infiltrate of cells in its base, depending on the age of

Figure 6.36 Mucous membrane pemphigoid. Scar tissue is present in the dermis beneath the subepidermal blister. Because blisters have a tendency to recur at the site of a previous lesion, scarring may be present in the dermis beneath a 'new' blister. (H&E)

the lesion. In lesions of less than 48 hours' duration, there are neutrophil microabscesses in the dermal papillae resembling those seen in dermatitis herpetiformis.²³⁹² With increasing age of the lesion, there are increasing numbers of eosinophils and later of lymphocytes and a reducing number of neutrophils. There are always fewer eosinophils than in bullous pemphigoid.²²⁹⁵

Scarring may be present even in early lesions if the biopsy site corresponds to an area of previous blister formation and subsequent scarring (Fig. 6.36). The earliest stages of scarring may be detected by examination under polarized light. New collagen bundles are arranged parallel to the surface rather than in the usual haphazard distribution.

The presence of a sebaceous gland within the blister is said to be a clue to the diagnosis of cicatricial pemphigoid.²³⁹³ It presumably results from extension of the blister along the edge of the pilosebaceous unit.

Direct IF shows linear deposits of IgG and often of C3 along the basement membrane zone in approximately 80% of cases.^{2394,2395} The yield is higher in buccal mucosa than in skin.^{2347,2396} A similar band often extends along the basement membrane of the appendages; it has also been reported in a similar position in the mucous glands of the oropharynx.²³⁹⁷ IgA and other immunoglobulins may also be present in approximately 20% of cases,²³⁹² but only rarely is IgA the only immunoglobulin present (discussed previously).^{2128,2394} Linear IgE deposition is found in some examples of mucous membrane pemphigoid, as it is in a portion of bullous pemphigoid cases.²³⁹⁸ Using salt-split skin, two different patterns can be seen.²³⁷⁶ In the antiepiligrin group (discussed previously), the deposits are found on the dermal side, as in EBA, whereas in the other group they are on the epidermal side.

Circulating antibodies to basement membrane zone were initially found in only 20% of cases, but the use of multiple substrates, including salt-split skin, and/or the use of concentrated serum samples will increase considerably the number of positives obtained.²³⁹⁹⁻²⁴⁰¹ IgA antibodies are frequently present.^{2402,2403} Their presence may signify a more severe and persistent disease.²⁴⁰⁴ Serial titers of these circulating IgG and IgA antibodies correlate with disease activity.²⁴⁰¹ Circulating pemphigus-like antibodies have been demonstrated in several cases; they are of doubtful significance and probably the result of epitope spreading.²⁴⁰⁵ AECp can only be distinguished from EBA on indirect IF by the use of two recently described techniques – 'knockout' skin substrate and the fluorescent overlay mapping technique.²⁴⁰⁶

Electron microscopy

Most studies have shown that the split occurs in the lower lamina lucida, although it has been suggested that a lower level (the lamina densa) would be more in keeping with the presence of scarring.^{2407,2408} Ultrastructural studies that were carried out prior to the recognition of the two distinct immunopathological groups need to be interpreted with this in mind.²⁴⁰⁸ In the antiepiligrin group, the deposits are found in the lower lamina lucida and in the adjacent lamina densa, whereas in the other group they are at a higher level in the lamina lucida, spilling onto the hemidesmosomes.^{2348,2349} Further studies are needed to confirm these findings.

Differential diagnosis of mucous membrane pemphigoid

The microscopic differential diagnosis includes many of the subepidermal immunobullous diseases, and given the variability of antigenic targets in cases qualifying as mucous membrane pemphigoid, some examples can represent, in effect, 'mucosal' subtypes of *bullous pemphigoid*, *linear IgA disease*, or *epidermolysis bullosa acquisita*. Others with unique antigenic targets do not precisely fit into these categories but produce sufficient microscopic overlap that only more sophisticated mapping studies, immunoblotting, or ELISA methods can allow precise categorization. Nevertheless, even in some of these latter cases, more 'traditional' immunofluorescence methods can be used successfully in diagnosis. For example, a study of anti-laminin-332 mucous membrane pemphigoid showed that a combination of direct IF, showing an 'n' serration pattern of basement membrane zone IgG deposition, and salt-split indirect IF, showing antibody binding at the floor of the subepidermal separation, separates this form of the disease from other types of mucous membrane pemphigoid and from EBA.²⁴⁰⁹

In our experience, a more common diagnostic problem is the categorization of a case of conjunctivitis or desquamative gingivitis as cicatricial pemphigoid, pemphigus vulgaris, or *mucosal lichen planus*. There can be considerable overlap in the clinical presentations of these diseases. The microscopic task is made more difficult by the technical problems inherent in biopsy of these two sites, especially in the case of friable tissue. However, band-like subepithelial lymphocytic inflammation clearly favors lichen planus and suprabasilar acantholysis points to a diagnosis of pemphigus vulgaris, whereas a more mixed inflammatory reaction and scarring tend to favor cicatricial pemphigoid. In this situation, assuming that an intact specimen is submitted, direct IF can be immensely helpful in that positive linear basement membrane zone IgG, C3, or IgA deposition favors cicatricial pemphigoid, whereas IgM-positive Civatte bodies and a shaggy fibrin band are characteristic of lichen planus, and intercellular IgG and C3 deposition are typical for pemphigus vulgaris. Alessi *et al.* used reflectance confocal microscopy for the *in vivo* evaluation of desquamative gingivitis and identified characteristic patterns that can identify each of these diseases. With this method, mucous membrane pemphigoid shows a separation at the dermal–epidermal junction filled with bright structures that are interpreted as erythrocytes.⁸⁵⁵

OCULAR CICATRICAL PEMPHIGOID

Ocular cicatricial (mucous membrane) pemphigoid is a rare disease characterized by the linear deposition of IgG and/or IgA along the basement membrane zone of conjunctival biopsies. The disease appears to be unique on the basis of a 45-kDa antigen that binds IgA antibodies.^{2394,2410} It is possible that this is an antigenically heterogeneous entity.²³⁶⁰ Plectin has been identified as another antigen.

A case of ocular cicatricial pemphigoid in which oral pemphigus vulgaris also occurred has been reported.²⁴¹¹

LOCALIZED CICATRICAL PEMPHIGOID

Localized cicatricial pemphigoid (Brunsting–Perry type) is characterized by the occurrence of one or more scarring, plaque-like lesions, usually on the head and neck, but without involvement of mucous membranes, even during prolonged follow-up.^{2412–2416} The temple is the most frequent site,^{2417,2418} but lesions have been reported elsewhere²⁴¹⁹ and also in tissue transplanted to the site of a pre-existing lesion.²⁴¹⁴ The exact relationship of this condition to mucous membrane pemphigoid is speculative, although they are thought to be closely related diseases.²⁴¹⁵ Rare cases may progress to a generalized bullous eruption that heals with scarring, but in contrast to mucous membrane pemphigoid, there is no mucous membrane involvement. The term ‘disseminated cicatricial pemphigoid’ has been used for these cases.²⁴²⁰ The First International Consensus on Mucous Membrane Pemphigoid stated that such cases should be classified as a separate clinical entity, distinct from mucous membrane pemphigoid.²²⁹⁹ Other cases have been claimed to represent localized acquired epidermolysis bullosa.²⁴²¹ The exact nosological position of this ‘entity’ must await further studies. In one case, antibodies to a 180-kDa antigen were present.²⁴²² Two recent cases of Brunsting–Perry pemphigoid had antibodies toward laminin-332, supporting the relationship to mucous membrane pemphigoid,^{2423,2424} although one of these cases also had antibodies to BP230 and desmoplakins I/II.²⁴²³ Still another case showed antibodies against the 290-kDa polypeptide along the lamina densa – a feature associated with epidermolysis bullosa acquisita.²⁴²⁵

Localized cicatricial pemphigoid should also be distinguished from ‘localized pemphigoid’, which is a variant of bullous pemphigoid in which lesions are localized to one area, such as the vulva,^{1582,1583} pretibial region, a stoma site, or the palms and soles.^{1581,1592} In contrast to localized cicatricial pemphigoid, the lesions in ‘localized pemphigoid’ do not scar.

Treatment is usually carried out with topical or intralesional corticosteroid. Systemic corticosteroids are not often required. It frequently responds to dapsone.²⁴²⁶

Histopathology²⁴¹⁴

There is a subepidermal blister with a mixture of neutrophils, eosinophils, and lymphocytes, similar to that seen in cicatricial pemphigoid. The proportion of the various cell types in the infiltrate depends on the age of the lesion biopsied. Small papillary microabscesses are present in lesions less than 48 hours old (Fig. 6.37).²⁴¹⁷ There is variable fibrosis in the dermis, depending on the presence of a previous blister at the site of biopsy.

In the pretibial form of ‘localized pemphigoid’, there is only a sparse dermal inflammatory cell infiltrate associated with neovascularization of the papillary dermis.¹⁵⁸⁵ There may be some fibrosis of the dermis, but this is rarely a prominent feature.

Immunofluorescence of localized cicatricial pemphigoid usually shows basement membrane zone IgG and/or C3.²⁴¹⁴ Indirect IF for circulating antibodies is usually negative.²⁴¹⁴

Electron microscopy

Ultrastructural studies have shown that the blister forms below the basal lamina.²⁴¹³ The basal lamina and anchoring fibrils are well preserved and attached to the intact epidermis, which forms the roof of the blister.²⁴¹³

DEEP LAMINA LUCIDA (ANTI-p105) PEMPHIGOID

Deep lamina lucida (anti-p105) pemphigoid appears to be a unique nonscarring, subepidermal bullous dermatosis with extensive bullae

Figure 6.37 Localized cicatricial pemphigoid. A neutrophil microabscess is present in a dermal papilla, similar to the picture in dermatitis herpetiformis. (H&E)

and erosions on mucous membranes and skin resembling toxic epidermal necrolysis or pemphigus vulgaris.^{2427–2429} The target antigen has a molecular weight of 105 kDa.

Histopathology

There is a subepidermal blister with neutrophils in the papillary dermis, resembling dermatitis herpetiformis. Direct IF shows linear IgG and C3 along the basement membrane zone. The deposits are in the lower lamina lucida, reacting with a 105-kDa antigen.^{2427,2428} The antigen is not the 105-kDa γ_2 chain of laminin 5.²⁴³⁰

ANTI-LAMININ γ_1 PEMPHIGOID (ANTI-p200 PEMPHIGOID)

Formerly termed anti-p200 pemphigoid, this unique subepidermal blistering disease has the clinical appearance of bullous pemphigoid, dermatitis herpetiformis, inflammatory epidermolysis bullosa acquisita, or linear IgA bullous dermatosis, combined with linear deposits of IgG and C3 along the basement membrane.²⁴³¹ The disease occurs primarily in middle-aged to older adults and tends to be more prominent in males.²⁴³² There are disseminated small blisters and erosions.²⁴³³ Palmo-plantar involvement also occurs. Large tense bullae may also be the dominant lesion.²⁴³⁴ In contrast to conventional bullous pemphigoid, this disorder tends to have more frequent mucous membrane and head and neck involvement and is prone to form milium scars.²⁴³² It is associated with psoriasis in perhaps as many as one-third of patients.^{2432,2435} The antibodies, usually of the IgG4 subclass, are directed against a 200-kDa protein in the lower lamina lucida that is distinct from either laminin 5 or type VII collagen.^{2433,2436–2438} This 200-kDa protein has now been identified as laminin γ_1 , an extracellular matrix glycoprotein.^{2439,2440}

In a recently reported case, the condition was associated with IgA antibodies.²⁴⁴¹ A novel ELISA method has been developed for the diagnosis of this unusual form of pemphigoid.²⁴⁴² However, using an *ex vivo* model, one group of investigators found that although autoantibodies in patient sera are indeed pathogenic, this pathogenicity does not appear to be mediated by autoantibodies against laminin γ_1 .²⁴⁴⁰ One study reported a patient with a nonscarring blistering eruption of skin and mucous membranes who had autoantibodies to both p200 and the α_3 chain of laminin 5.²⁴⁴³ In a similar case, the antibody to laminin 5 was to the γ_2 subunit.²⁴⁴⁴ Still another reported patient with anti-p200 pemphigoid developed autoantibodies against the α_3 chain of laminin

5, 1.5 years after the original diagnosis, but without a change in the clinical appearance of the disease.²⁴⁴⁵ These occurrences may well have been the result of epitope spreading.

Cases have been reported that were successfully treated with systemic corticosteroid and dapsone^{2435,2446} or with dapsone alone.²⁴³²

Histopathology

A study of 10 biopsies from seven patients by Rose *et al.* in 2007 found subepidermal blistering in all cases with a moderate to dense inflammatory infiltrate in the upper dermis.²⁴⁴⁷ The infiltrate was composed almost exclusively of neutrophils in 6 biopsies and contained a mixture of neutrophils and eosinophils in the remaining 4 biopsies. In three specimens, microabscess formation was present in the papillary dermis adjacent to the main blister.²⁴⁴⁷ Neutrophilic and eosinophilic spongiosis occurred in 5 and 3 biopsies, respectively.²⁴⁴⁷

Direct IF of perilesional skin shows linear deposits of IgG and C3 at the dermoepidermal junction, whereas indirect IF of patient sera demonstrates circulating IgG4 autoantibodies binding to the dermal side of salt-split skin.^{2433,2446,2447} Laser scanning confocal microscopy was used to find tissue-bound antibodies in the case associated with IgA; the deposits colocalized with laminin 332 (laminin 5) and were found above type IV collagen.²⁵³

Electron microscopy

Ultrastructural studies have localized p200 to the lamina lucida–lamina densa interface.²⁴³³

BULLOUS URTICARIA

Bullae are an uncommon manifestation of urticaria and result from severe edema of the papillary dermis. Neutrophils and eosinophils are present in the upper dermis; sometimes a mixed infiltrate of lymphocytes and eosinophils is present.

BULLOUS ACUTE VASCULITIS

If bullae form in acute vasculitis, they are sometimes hemorrhagic. The vessels in the underlying dermis show the typical features of an acute vasculitis. Leukocytoclasia may be a conspicuous feature. A vasculitis is usually present in the bullous lesions associated with septicemia caused by *Vibrio vulnificus*²⁴⁴⁸ and, rarely, by *Escherichia coli*,²⁴⁴⁹ *Yersinia enterocolitica*, and *Morganella morganii*.²⁴⁵⁰ Subepidermal bullae have also been reported in the toxic shock syndrome.²⁴⁵¹

BULLOUS LUPUS ERYTHEMATOSUS

A vesiculobullous eruption is an uncommon manifestation of SLE. The lesions vary in appearance from herpetiform vesicles to large hemorrhagic bullae. Sometimes the lesions are limited to sun-exposed areas of the body.

Bullous lupus erythematosus shares with EBA the presence of autoantibodies to type VII collagen, although not all patients have these autoantibodies.

Bullae are exceedingly rare in dermatomyositis. They have also been reported in a patient with Sjögren's syndrome who had circulating antibodies to type VII collagen.²⁴⁵²

Histopathology²⁴⁵³

The appearances closely resemble dermatitis herpetiformis with subepidermal splitting and papillary microabscesses (Fig. 6.38). Nuclear dust is prominent in the papillae and sometimes around superficial blood vessels. The neutrophils tend to extend more deeply in the papillary dermis and around vessels than they do in dermatitis herpe-

Figure 6.38 Bullous lupus erythematosus. Neutrophils are present in the superficial dermis in a more dispersed arrangement than in dermatitis herpetiformis. There is a small subepidermal blister. (H&E)

tiformis. Vacuolar change is not usually present, although occasional Civatte bodies are sometimes seen. Direct IF often shows linear IgG deposition along the dermal–epidermal interface (Fig. 6.39). Occasionally, one can observe IgG antibody directed toward keratinocyte nuclei (i.e., an antinuclear antibody); this antibody may be unmasked during a saline-splitting procedure (see Chapter 3 and Fig. 3.31).

Immunoelectron microscopy shows the deposits (IgG, C3, and often IgA) deep to the anchoring fibrils in the upper dermis.

ERYSIPELAS

In erysipelas, subepidermal blisters may form as a result of massive edema in the upper dermis. Elongated rete ridges may bridge the blister and connect with the underlying dermis. The neutrophilic infiltrate is usually only mild, although there are numerous extravasated erythrocytes.

SWEET'S SYNDROME

Bullae are quite uncommon in Sweet's syndrome. Sometimes there is severe edema of the upper dermis mimicking early blister formation, but the clinical appearances suggest an urticarial plaque, not a blister. There is a heavy infiltrate of neutrophils in the upper and mid dermis, often with leukocytoclasia. There is no fibrinoid change in vessel walls.

EPIDERMOLYSIS BULLOSA ACQUISITA

Neutrophils are present in the dermis in the inflammatory variant of this disease (see p. 164).

SUBEPIDERMAL BLISTERS WITH MAST CELLS

BULLOUS MASTOCYTOSIS

Bullous lesions are an uncommon manifestation of mastocytosis in neonates and infants (see p. 1145). There are usually numerous mast cells in the dermis beneath the blister.

Figure 6.39 Bullous lupus erythematosus. In this example, direct immunofluorescence shows linear IgG deposition along the dermal–epidermal junction.

MISCELLANEOUS BLISTERING DISEASES

The *miscellaneous category* of blistering diseases includes several very rare entities in which the anatomical level of the split is variable or the disease does not fit appropriately into one of the categories of subepidermal blistering diseases already mentioned. Penicillamine may produce blisters at different anatomical levels in the epidermis, resembling either pemphigus foliaceus or pemphigus vulgaris. An unusual bullous eruption has been reported in a patient receiving intravenous trimethoprim–sulfamethoxazole.²⁴⁵⁴ The blisters occurred below the lamina densa but produced no scarring. On light microscopy they were subepidermal with a light, mixed inflammatory cell infiltrate.²⁴⁵⁴

Blisters have been reported on the knees from repeated kneeling in church ('prayer' or 'pew' blisters).²⁴⁵⁵ No histology was performed.

Unusual blisters resembling bubble wrap developed after occupational skin injury with 35% hydrogen peroxide.²⁴⁵⁶ Numerous vacuolar structures were observed in the epidermis, dermis, and subcutis. The vacuoles were considered to be 'oxygen bubbles'.²⁴⁵⁶

The bullous lesions that develop rarely in diabetes mellitus (see p. 574) may be subepidermal or intraepidermal; so too may the blisters associated with non-01 *Vibrio cholerae* infection (see p. 643). Infection may have been the precipitating cause of two cases reported as IgE bullous disease.²⁴⁵⁷ There were subepidermal bullae resembling bullous pemphigoid but no immunoreactants, other than deposits of IgE on inflammatory cells within the dermis.²⁴⁵⁷

Bullae may be a manifestation of the rare genodermatoses pachyonychia congenita (see p. 298) and Kindler's syndrome (see p. 76). Small, hemorrhagic blisters have been reported in one case of Wilson's disease.²⁴⁵⁸ A subepidermal bullous eruption has been reported in patients with reflex sympathetic dystrophy.²⁴⁵⁹

The following entities are discussed further here:

- Drug overdose-related bullae
- Methyl bromide-induced bullae
- Etretinate-induced bullae
- PUVA-induced bullae
- Cancer-related bullae
- Lymphatic bullae.

DRUG OVERDOSE-RELATED BULLAE

Bullae, tense vesicles, erosions, and dusky erythematous plaques may develop at sites of pressure in patients with drug-induced or carbon monoxide-induced coma, particularly if the coma is deep.^{2460,2461} Drugs involved have included morphine, heroin, methadone, barbiturates,²⁴⁶² imipramine, carbamazepine,²⁴⁶³ amitriptyline,²⁴⁶⁴ clobazam,²⁴⁶⁵ alcohol,²⁴⁶⁶ and diazepam.²⁴⁶⁷ Rarely, this entity has developed in association with other neurological disorders;²⁴⁶⁷ it followed treatment with the β -adrenergic antagonist atenolol in a patient with pheochromocytoma.²⁴⁶⁸ Similar blisters have developed in patients with a coma due to diabetic ketoacidosis²⁴⁶⁹ and a traffic accident.²⁴⁷⁰ This condition has also been reported in a noncomatose patient who was taking a high dose of benzodiazepine daily.²⁴⁷¹

The lesions are believed to result from tissue ischemia, which in turn is related to local pressure and to systemic hypoxia.²⁴⁷²

Histopathology^{2472–2475}

The blisters that form are predominantly subepidermal, but there is also spongiosis in the overlying epidermis that may lead to the formation of intraepidermal vesicles as well. There is focal necrosis of keratinocytes in and adjacent to the acrosyringium; sometimes the epithelium in the pilosebaceous follicles also shows focal necrosis. The secretory cells of the sweat glands beneath the bullae are necrotic (Figs. 6.40A and 6.40B). The basement membrane of the sweat glands may also be destroyed, but the myoepithelial cells usually survive. In the dermis, there is only a sparse inflammatory cell infiltrate that includes some neutrophils. Some arterioles show necrosis of their walls with a mild perivascular infiltrate of neutrophils. Thrombi are not usually seen, but they are more common in non-drug-induced coma.²⁴⁷⁶

METHYL BROMIDE-INDUCED BULLAE

A vesiculobullous eruption has been reported following occupational exposure to high concentrations of methyl bromide used in fumigation.²⁴⁷⁷

Histopathology²⁴⁷⁷

The bullae induced by methyl bromide are subepidermal in location and associated with marked edema of the upper dermis. The dermal infiltrate is composed of neutrophils, eosinophils, and a few lymphocytes. The infiltrate is distributed around blood vessels in the upper dermis.

Figure 6.40 Drug overdose-related bullae. (A) There is a re-epithelializing subepidermal bulla, with a necrotic overlying epidermis. (B) Necrosis of the secretory portions of eccrine sweat glands is also evident.

Another feature of this entity is the presence of spongiosis of the epidermis and necrosis of epidermal keratinocytes. Neutrophils infiltrate the epidermis.

Similar changes have been reported following skin exposure to nitrogen and sulfur mustard.²⁴⁷⁸

ETRETINATE-INDUCED BULLAE

Increased skin fragility and subepidermal blistering are rare complications of therapy with etretinate.²⁴⁷⁹ The blisters rapidly ulcerate; they are followed by some scarring.

Histopathology²⁴⁷⁹

Intact blisters are difficult to obtain. Clefting appears to occur at the dermoepidermal junction. The overlying epidermis may show spongi-

osis. The dermal infiltrate includes plasma cells, eosinophils, and neutrophils.

PUVA-INDUCED BULLAE

Blisters may develop on the limbs in 10% of patients receiving therapy with psoralens plus long-wave ultraviolet light (PUVA).²⁴⁸⁰ The lesions appear to result from friction and minor trauma. The mechanism remains to be determined, although the blisters apparently develop as a result of damage to the basal and suprabasal layers of the epidermis.²⁴⁸⁰ Blisters have also been reported following ruby laser treatment for incontinentia pigmenti.²⁴⁸¹

Histopathology²⁴⁸⁰

The blistering appears to form in the basal layer of the epidermis because damaged basal cells are sometimes seen in the base of the blisters. There is swelling and destruction of keratinocytes in the overlying epidermis. Apoptotic cells ('sunburn cells') are sometimes present. The dermis contains a very sparse, mixed inflammatory cell infiltrate.

CANCER-RELATED BULLAE

Several patients with cancer have developed bullae in association with gyrate lesions.^{2482,2483} Uncommonly, the bullae are related to trauma.²⁴⁸³ Bullae have been reported in a patient with multiple myeloma, but there were no gyrate lesions.^{2484,2485} An unusual pustular eruption, with epidermal spongiosis containing immature myeloid cells, has been reported in infants with Down syndrome and a congenital leukemoid reaction.^{356,357}

Not included in this category are the bullous eruptions, resembling bullous pemphigoid and epidermolysis bullosa acquisita, that sometimes develop in patients with cancer. A case of Waldenström macroglobulinemia has been reported that clinically consisted of pruritic papules rather than bullae but on direct IF showed IgM basement membrane zone deposits.²⁴⁸⁶

Histopathology²⁴⁸³

The cancer-related bullae with gyrate lesions are usually subepidermal in location, and the inflammatory cell infiltrate in the dermis is mild and of mixed type. Direct IF may show IgG and C3 in the basement membrane zone.²⁴⁸³

LYMPHATIC BULLAE

Subepidermal bullae are a very rare complication of lymphedema or of a lymphatic fistula.^{2487,2488} Uncommonly, vesicular lesions are due to markedly dilated lymphatics in the papillary dermis.²⁴⁸⁹ Interference with lymphatic drainage has been postulated as a possible mechanism for the bullae that have been described over laser-resurfaced skin.²⁴⁹⁰

The blisters that develop near fractures, adjacent to joints or areas of limited skin mobility, result from massive subepidermal edema leading to separation of the epidermis, which becomes necrotic.²⁴⁹¹ They are mentioned here for completeness.

INTRODUCTION

The granulomatous reaction pattern is defined as a distinctive inflammatory pattern characterized by the presence of granulomas. Granulomas are relatively discrete collections of histiocytes or epithelioid histiocytes with variable numbers of admixed multinucleate giant cells of varying types and other inflammatory cells.¹ Conditions in which there is a diffuse infiltrate of histiocytes within the dermis, such as lepromatous leprosy, are not included in this reaction pattern. The group is subdivided by way of

- the arrangement of granulomas;
- the presence of accessory features such as central necrosis, suppuration, or necrobiosis; and
- the presence of foreign material or organisms.

It is difficult to present a completely satisfactory classification of the granulomatous reactions.² As Hirsh and Johnson remark in their review of the subject, “Sometimes a perfect fit can be achieved only with the help of an enlightened shove.”³ Many conditions described within this group may show only nonspecific changes in the early evolution of the inflammatory process and in a late or resolving stage show fibrosis and nonspecific changes without granulomas. Occasionally, a variety of granuloma types may be seen in one area, such as in reactions to foreign bodies or around ruptured hair follicles.

It is necessary in any granulomatous dermatitis to exclude an infectious cause. In some countries, up to 90% of granulomas have an infectious etiology.⁴ Culture of fresh tissue as well as histological search increases the chances of identifying a specific infectious agent. The time-consuming examination of multiple sections may be necessary to exclude such a cause. Special stains for organisms may be indicated. Occasionally, fungi are shown only by silver stains, such as Grocott methenamine silver, and not by PAS staining. All granulomas should be examined under polarized light to detect or exclude birefringent foreign material.

Considerable advances have been made in the understanding of the formation and maintenance of granulomas in tissue reactions and the roles played by B and T lymphocytes and cytokines.⁵⁻⁸ It is also clear that there are several types of macrophages in granulomas, particularly at an ultrastructural level.⁹ The different forms of multinucleate giant cells seen in granulomas may simply reflect the types of cytokines being produced by the component cells.¹⁰ This new information has not so far been shown to be useful in routine diagnostic problems. The glioma-associated oncogene homologue *gli-1* is expressed in lesional skin in patients with cutaneous sarcoidosis, granuloma annulare, and necrobiosis lipoidica.¹¹ These findings provide a rationale for clinical trials of inhibitors of *gli-1* signaling, including tacrolimus and sizolimus, for the treatment of these conditions.¹¹ Polymerase chain reaction (PCR) techniques have proved useful in detecting infectious agents in tissue sections, particularly mycobacterial species.¹²⁻¹⁶

The following types of granulomas form the basis of the subclassification of diseases in this reaction pattern:

- **Sarcoidal:** Granulomas composed of epithelioid histiocytes and giant cells with a paucity of surrounding lymphocytes and plasma cells ('naked' granulomas)
- **Tubercloid:** Granulomas composed of epithelioid histiocytes, giant cells of Langhans and foreign body type with a more substantial rim of lymphocytes and plasma cells and sometimes showing central 'caseation' necrosis. Granulomas have a tendency to confluence
- **Necrobiotic (collagenolytic):** Granulomas are usually poorly formed and there are collections, and a more diffuse array, of histiocytes, lymphocytes, and giant cells with associated 'necrobiosis' (collagenolysis). The inflammatory component may be admixed with the 'necrobiosis' or form a palisade around it

- **Suppurative:** Granulomas composed of epithelioid histiocytes and multinucleate giant cells with central collections of neutrophils. Chronic inflammatory cells are usually present at the periphery of the granulomas
- **Foreign body:** Granulomas composed of epithelioid histiocytes, multinucleate (foreign body-type) giant cells, and variable numbers of other inflammatory cells. There is identifiable foreign material, either exogenous or endogenous in origin
- **Xanthogranulomas:** Granulomas composed of numerous histiocytes with foamy/pale cytoplasm with a variable admixture of other inflammatory cells and some Touton giant cells
- **Miscellaneous:** A category in which the granulomas may be variable in appearance or do not always fit neatly into one of the previous categories.

Many of the conditions exhibiting a granulomatous tissue reaction are discussed in other chapters; they are mentioned only briefly.

The various granulomatous diseases are discussed, in order, according to the classification listed previously.

SARCOIDAL GRANULOMAS

Sarcoidal granulomas are found in sarcoidosis and in certain types of reaction to foreign materials and squames.

The prototypic condition in this group is sarcoidosis. Sarcoidal granulomas are discrete, round to oval, and composed of epithelioid histiocytes and multinucleate giant cells that may be of either Langhans or foreign body type. Generally, the type of multinucleate histiocyte present in a granuloma is not helpful in arriving at a specific histological diagnosis. Giant cells may contain asteroid bodies, conchoidal bodies (Schaumann bodies), or crystalline particles. Typical granulomas are surrounded by a sparse rim of lymphocytes and plasma cells, and only occasional lymphocytes are present within them. Consequently, they have been described as having a 'naked' appearance. Although the granulomas may be in close proximity to one another, their confluence is not commonly found. With reticulin stains, a network of reticulin fibers is seen surrounding and permeating the histiocytic cluster.

Sarcoidal granulomas can be found in the following circumstances:

- Sarcoidosis
- Blau's syndrome
- Foreign body reactions (Table 7.1)
- Secondary syphilis
- Sézary syndrome¹⁷
- Metastatic Crohn's disease
- Orofacial granulomatosis
- Granuloma annulare (sarcoidal type)
- Herpes zoster scars¹⁸
- Systemic lymphomas^{19,20}
- Breast cancer²¹
- Common variable immunodeficiency (see p. 214)
- X-linked hyper-IgM syndrome²²
- Tumor necrosis factor- α (TNF- α) inhibitors²³
- Nijmegen breakage syndrome.²⁴

Sarcoidal granulomas are exceedingly rare in secondary syphilis (see p. 675), Sézary syndrome, herpes zoster scars (see p. 728), systemic lymphomas, and breast cancer. The granulomas in metastatic Crohn's disease and orofacial granulomatosis are often of mixed sarcoidal and tubercloid types. These diseases are considered with the miscellaneous granulomatous diseases (see p. 210). The sarcoidal variant of

Table 7.1 Foreign material producing sarcoidal granulomas

Silica (including windshield glass)
Silicone
Tattoo pigments
Zirconium
Beryllium
Zinc
Acrylic or nylon fibers
Keratin from ruptured cysts (uncommon)
Exogenous ochronosis
Sea-urchin spines
Cactus
Wheat stubble
Desensitizing injections
Ophthalmic drops (sodium bisulfite)
Sulfonamides
Interferon injection sites

granuloma annulare is discussed with other types of this condition (see p. 202). They are not considered further in this section.

SARCOIDOSIS²⁵

Sarcoidosis is a multisystem disease that may involve any organ of the body but most commonly affects the lungs, lymph nodes (mediastinal and peripheral), skin, liver, spleen, and eyes.^{26–29} Central nervous system involvement is uncommon.³⁰ There is an increased incidence of sarcoidosis in people of Irish and Afro-Caribbean origin.³¹ Cutaneous sarcoidosis is rare in Asia.³²

Between 10% and 35% of patients with systemic sarcoidosis have cutaneous lesions.^{33–35} Although sarcoidosis is usually a multiorgan disease, chronic cutaneous lesions may be the only manifestation.³⁶ The skin lesions may be specific, showing a granulomatous histology, or nonspecific. The most common nonspecific skin lesion is erythema nodosum, which is said to occur in 3–25% of cases.³³ Sarcoidosis of the knees is frequently associated with erythema nodosum.³⁷ An erythema nodosum-like eruption with the histological changes of sarcoidosis has also been described.³⁸ Sarcoidosis predominantly affects adults; skin lesions are rarely seen in children.^{39–42} There are reports of its occurrence in monozygotic twins.⁴³ Children presenting before the age of 4 years usually have the triad of rash, uveitis, and arthritis,^{44,45} without apparent pulmonary involvement.⁴⁵ This early onset sarcoidosis (OMIM 609464) is caused by mutations in the *NOD2/CARD15* gene on chromosome 16q12, similar to Blau’s syndrome (see later). Vasculitis may also occur in this group.⁴⁵

A diversity of clinical forms of cutaneous sarcoidosis occurs. These forms include the following:

- Papules,⁴⁶ plaques,⁴⁷ and nodules, which may be arranged in an annular or serpiginous pattern
- A maculopapular eruption associated with acute lymphadenopathy, uveitis, or pulmonary involvement
- Plaques with marked telangiectasia (angiolupoid sarcoidosis)
- Lupus pernio, consisting of violaceous nodules, particularly on the nose, cheeks, and ears^{48,49}
- Nodular subcutaneous sarcoidosis.^{50–56} This form was diagnosed in 10 of 85 patients (11.8%) in one series.⁵⁷ Lesions were most

frequently located on the extremities, particularly the forearms, where indurated linear bands were sometimes found. It may occur on the breast, mimicking breast carcinoma.⁵⁸ Subcutaneous sarcoidosis is the only specific subset of cutaneous sarcoidosis frequently associated with systemic disease.⁵⁹

- A miscellaneous group that includes cicatricial alopecia,^{60,61} an acral form,⁶² ichthyosiform sarcoidosis,^{63–65} ulcerative,^{66,67} necrotizing, morpheaform, and mutilating forms,^{68–72} verrucous lesions,^{73–75} atrophic lesions,⁷⁶ discoid lupus erythematosus-like lesions,⁷⁷ and erythroderma.⁷⁸ Cutaneous sarcoidal granulomas have also been reported at the site of cosmetic filler injections in patients with or without systemic sarcoidosis.^{79,80}

This miscellaneous group represents rare cutaneous manifestations of sarcoidosis. Lupus pernio may resolve with fibrosis and scarring and is often associated with involvement of the upper respiratory tract and lungs.⁸¹ Oral, eyelid, and scrotal lesions have been reported.^{82–84} The majority of skin lesions resolve without scarring. Hypopigmented macules without underlying granulomas have been described, particularly in patients of African descent,⁸⁵ although larger hypopigmented patches with underlying granulomas have also been described.⁸⁶ Other rare presentations have included leonine facies,⁸⁷ faint erythema,⁸⁸ palmar erythema,⁸⁹ vasculitis,⁴⁵ alopecia,^{90,91} and lesions confined to the vulva.⁹² Sarcoidosis may follow the use of interferon therapy (IFN- α) for melanoma⁹³ or hepatitis C.^{94–100} Sometimes the lesions are limited to injection site scars in these patients.¹⁰¹ Cutaneous sarcoidosis has also developed after treatment with pegylated IFN.¹⁰² It may also occur in patients with hepatitis C unrelated to treatment.¹⁰³ It has also followed bacillus Calmette–Guérin (BCG) vaccination.¹⁰⁴ A seasonal, photo-induced variant of sarcoidosis has been rarely described.¹⁰⁵ There have been several reports of cutaneous sarcoidosis, or sarcoid-like granulomas, associated with TNF- α inhibitors.^{23,106–108} This is particularly problematic because these agents have also been used for treatment of the disease.^{109–112}

It is generally considered that the presence of cutaneous lesions in association with systemic involvement is an indicator of more severe disease. Skin lesions may occur in scars^{113–116} following trauma (including surgery, desensitizing injection sites, and venepuncture),^{117–119} cosmetic tattoos,^{120,121} irradiation, and chronic infection. In some cases, these lesions may be the first manifestation of sarcoidosis.^{122,123} Other cases do not appear to be related to systemic sarcoidosis and may be a sarcoidal reaction to a foreign body.¹²⁴ Dermoscopy has been used to enhance the diagnosis of cutaneous sarcoidosis; findings suggesting granulomatous processes such as sarcoidosis include grouped translucent orange globules and linear vessels of various diameters.¹²⁵

Various systemic diseases have been reported in association with cutaneous sarcoidosis. The association in many of these conditions is probably fortuitous. They include B-cell chronic lymphocytic leukemia,¹²⁶ cutaneous lymphoma,^{127,128} pyoderma gangrenosum,¹²⁹ hypoparathyroidism,¹³⁰ cryptococcal infection,¹³¹ dermatomyositis,¹³² systemic sclerosis,¹³³ primary biliary cirrhosis,¹³⁴ autoimmune thyroiditis and/or vitiligo,^{135–137} polycythemia vera,¹³⁸ Wegener’s granulomatosis,¹³⁹ and HIV infection.¹⁴⁰ In cases of HIV infection, sarcoidosis may develop after the commencement of highly active antiretroviral therapy (HAART) and the restoration of some immune function.^{140,141} The term ‘immune restoration disease’ has been used for this circumstance.¹⁴² Subcutaneous granulomas and granulomatous tenosynovitis have been reported in an organ transplant recipient.¹⁴³ Various malignancies have been reported in patients with sarcoidosis, perhaps somewhat more often in those with cutaneous involvement; these neoplasms usually follow the diagnosis of sarcoidosis and include a variety of solid tumors as well as leukemias/lymphomas.¹⁴⁴

The etiology of sarcoidosis remains controversial, although an infectious origin has long been suspected.^{145,146} The main candidate is a cell wall-deficient form of an acid-fast bacillus similar, if not identical, to

Mycobacterium tuberculosis.¹⁴⁷ In one study, DNA sequences coding for the mycobacterial 65-kDa antigen were found in 11 of 35 cases of sarcoidosis,¹⁴⁸ whereas in a recent study, using only cutaneous specimens, mycobacterial DNA was demonstrated by PCR in 16 of 20 cases.¹⁴⁹ Nontuberculous (atypical) mycobacteria constitute the largest group of the species identified in this study.¹⁴⁹ Other findings supportive of a mycobacterial etiology are the beneficial effects of long-term tetracyclines¹⁵⁰ and the activation of a case following concurrent *Mycobacterium marinum* infection of the skin.¹⁵¹ In addition, CD4⁺ and CD8⁺ T-cell responses to mycobacterial epitopes are present in sites actively involved with sarcoidosis.¹⁵² In a study of 35 patients with sarcoidosis performed in 2005, *M. tuberculosis* rRNA was not detected in any case.¹⁵³ Based on these results, the authors concluded that this organism cannot be considered as the etiological agent of the disease.¹⁵³ The current evidence regarding a relationship between mycobacteria and sarcoidosis has been well summarized by Brownell *et al.*¹⁵⁴ These authors conclude that molecular analysis and studies of humoral and cellular immune responses support the idea that mycobacterial antigens are involved in at least some cases of sarcoidosis.¹⁵⁴

Another study concluded that there was no role for human herpesvirus type 8 (HHV-8) in the etiology, despite earlier reports suggesting a role.¹⁵⁵

Several studies have reported increased T-helper (Th)-1 cytokines with increased levels of TNF- α in patients with sarcoidosis.¹⁵⁶ Genes involved in Th-1 and Th-17 pathways are upregulated in skin lesions of sarcoidosis patients, at least when assessed at a single point in time.¹⁵⁷

The exact relationship of **Blau's syndrome** (OMIM 186580) to sarcoidosis is becoming clearer. It is characterized by the familial presentation of a sarcoid-like granulomatous disease involving the skin, uveal tract, and joints, but not the lung.¹⁵⁸ Camptodactyly is another defining sign.¹⁵⁹ Ichthyosis has been reported in one case.¹⁶⁰ Onset is in childhood, and the mode of inheritance is autosomal dominant. It shares with early onset sarcoidosis mutations in the *NOD2/CARD15* gene that maps to chromosome 16q12.^{161–163} Some patients with Crohn's disease also have mutations in this gene.

For limited cutaneous sarcoidosis, parenteral therapies have been the mainstay of therapy, but systemic therapy has been used for severe cutaneous disease, particularly if there is an aesthetic impact.¹⁶⁴ Therapies that have been used include corticosteroids, hydroxychloroquine, chloroquine, allopurinol, methotrexate, isotretinoin, mepacrine,¹⁶⁵ tacrolimus,¹⁶⁶ thalidomide,¹⁶⁴ various inhibitors of TNF- α such as adalimumab^{167,168} and infliximab,^{156,169} and thalidomide.¹⁷⁰ The various therapies used to treat cutaneous sarcoidosis have recently been reviewed.^{171,172}

Histopathology

There is a dermal infiltrate of naked sarcoidal granulomas (**Fig. 7.1**).¹⁷³ Granulomas may be present only in the superficial dermis or they may extend through the whole thickness of the dermis or subcutis, depending on the type of cutaneous lesion.¹⁷⁴ Interstitial and tuberculoid granulomas are uncommon.¹⁷³ Both perineural and periadnexal localization of the granulomas have been reported.^{173,175,176} A recent case of syringotropic sarcoidosis showed not only granulomas surrounding sweat glands but also decreased expression of dermicidin and aquaporin 5 in the involved sweat glands; both of these are expressed in sweat glands of normal controls.¹⁷⁷ A granulomatous vasculitis is exceedingly rare.^{178,179} Necrosis is not usually seen in granulomas but has been reported (**Fig. 7.2**).¹⁸⁰ Small amounts of fibrinous or granular material may be seen in some granulomas.²⁶ Increased mucin is present in approximately 20% of cases.¹⁷³ Fibrinoid necrosis is said to be quite common in the cutaneous lesions of black South Africans.³¹ Slight perigranulomatous fibrosis may be present, but marked dermal scarring is unusual except in lupus pernio or necrotizing and ulcerating lesions.

Figure 7.1 Sarcoidosis. The granulomas in the dermis are composed of epithelioid histiocytes and multinucleate giant cells with only a sparse infiltrate of lymphocytes at the periphery ('naked' granulomas). (H&E)

Figure 7.2 Sarcoidosis. A small area of necrobiosis is seen in this granuloma.

Fibrosis is often present in subcutaneous sarcoidosis. Touton-like giant cells may rarely be present.¹⁸¹

In subcutaneous sarcoidosis, the granulomas are usually limited to the subcutis without any dermal extension. The infiltrate is predominantly lobular with little or no septal involvement.⁵⁷ Discrete foci of necrosis may be present in the center of some granulomas in a few cases.⁵⁷ Perigranulomatous fibrosis, sometimes encroaching on the septa, is also present.¹⁸²

Overlying epidermal hyperplasia occurs in verrucous lesions,^{73,183} and hyperkeratosis occurs in the rare ichthyosiform variant.⁸⁹ A lichenoid variant has been reported. There was a thick band-like infiltrate of sarcoidal granulomas with basal apoptotic keratinocytes.¹⁸⁴ Otherwise, in most cases, the overlying epidermis is normal or atrophic.

Transepidermal elimination has been reported in sarcoidosis, and the histology shows characteristic elimination channels.^{133,185} In some cases, the round cell infiltrate surrounding the granulomas is more intense and the granulomas are less discrete. The diagnosis of sarcoidosis may then become one of exclusion.

Asteroid bodies and conchoidal bodies (Schaumann bodies) may be seen in multinucleate giant cells but are not specific for sarcoidosis and may occur in other granulomatous reactions including tuberculosis (Figs. 7.3A and 7.3B). Schaumann bodies, which are shell-like calcium-impregnated protein complexes, are much more common in the granulomas of sarcoidosis than in those of tuberculosis.¹⁸⁶ Mycobacterial antigens and lysosomal components have been found immunohistochemically within these bodies.¹⁵⁴ Birefringent material has been found in the granulomas from 22–50% of cases.^{173,174,187,188} Foreign bodies are more common in sarcoidal granulomas from sites subject to minor trauma, such as the knee.^{37,188} Furthermore, patients with sarcoidosis can develop granulomas at the sites of implantation of foreign material.^{189,190} Electron probe microanalysis has identified calcium, phosphorus, silicon, and aluminum in the birefringent material referred to previously. It is thought that the calcium salts are probably the precursors of Schaumann bodies. Another explanation for the material is that it represents foreign material inoculated during a previous episode of inapparent trauma leading to granuloma formation subsequently in a patient with sarcoidosis.^{191,192} Asteroid bodies are said by some to be formed from trapped collagen bundles¹⁹³ or from components of the cytoskeleton, predominantly vimentin intermediate filaments.¹⁹⁴

Biopsies taken from Kveim–Siltzbach skin test sites, sometimes used in the past for the diagnosis of sarcoidosis, show a variety of changes ranging from poorly formed granulomas with a heavy mononuclear cell infiltrate to small granulomas with few mononuclear cells. Measurement of the serum angiotensin-converting enzyme (ACE) level has now replaced this skin test.

Immunohistochemical marker studies have shown that the T lymphocytes expressing the suppressor/cytotoxic phenotype (CD8⁺) are found predominantly in the perigranulomatous mantle, whereas those expressing the helper/inducer phenotype (CD4⁺) are present throughout the granuloma.¹⁹⁵ B lymphocytes are also present in the mantle zone.

Immunofluorescence studies in some cases have shown IgM at the dermoepidermal junction, IgM within blood vessel walls, and IgG within and around the granuloma. A fibrin network is present within granulomas.¹⁹⁶

Differential diagnosis

When initially working up a case in which sarcoidosis is a potential diagnosis, polarization microscopy should be performed (while recognizing that sarcoidal lesions can sometimes show polarizable material), along with at least a fungal (PAS or methenamine silver) and acid-fast stain. Lesions proving to be infectious most often show a degree of suppuration (neutrophil accumulation) or tuberculoid

Figure 7.3 Sarcoidosis. (A) An asteroid body is present in the cytoplasm of a multinucleate giant cell. (B) A Schaumann body is present within this granuloma. (H&E)

granuloma formation. Other granulomatous lesions may show focal noncaseating granulomas, but in other areas there are often other types of granuloma. For example, the sarcoidal variant of granuloma annulare will often show other areas, in the same lesion or in other lesions, with interstitial infiltration or with mucinous necrobiosis. At the same time, it is important to note that lesions with the microscopic characteristics of necrobiosis lipoidica or granuloma annulare have been reported in patients with sarcoidosis on numerous occasions.^{197,198} So-called metastatic Crohn's disease can also show noncaseating granulomas, but a distinction can be made through an appreciation of lesional distribution and the association with inflammatory bowel disease. Another significant consideration in the differential diagnosis is tuberculoid leprosy, in which the granulomas can have a close resemblance to those of sarcoidosis. However, these granulomas tend to follow the course of nerves in the dermis, thereby often having elongated or 'sausage-shaped' contours. Degenerated nerve elements can often be seen within the granulomas, demonstrable with S100 immunostaining. Although *Mycobacterium leprae* organisms are rarely found, at least in pure tuberculoid leprosy, their presence can be inferred through PCR studies. A reticulin stain may

be helpful in difficult cases, in that there is a complex reticulin meshwork in the granulomas of sarcoidosis, but this feature is not observed in lesions of tuberculoid leprosy.

REACTIONS TO FOREIGN MATERIALS

A number of foreign substances and materials when introduced into the skin may induce a granulomatous dermatitis that histologically resembles sarcoidosis. They are listed in [Table 7.1](#).

Following some kind of trauma, silica may contaminate a wound in the form of dirt, sand, rock, or glass (including windshield glass from motor vehicles).¹⁹⁹ Papules and nodules arise in the area of trauma. The granulomas seen in the dermal reaction contain varying numbers of Langhans or foreign body giant cells, some of which may contain clear colorless particles. These may be difficult to see with routine microscopy but are birefringent in polarized light. The differentiation from true sarcoidosis may be difficult because granulomas sometimes develop in scars in sarcoidosis and the granulomas can contain birefringent calcite crystals. A sarcoidal reaction to identifiable foreign material does not exclude sarcoidosis. It has been suggested that particulate foreign material may serve as a nidus for granuloma formation in sarcoidosis.²⁰⁰ Silica-rich birefringent particles have also been described in lesions without a history of injury or silica exposure.²⁰¹ Energy-dispersive X-ray analysis techniques using scanning electron microscopy can be used to identify elements present in the crystalline material.²⁰² The granulomas are thought to develop as a response to colloidal silica particles and not as a result of a hypersensitivity reaction.²⁰³

A granulomatous dermatitis may occur in response to pigments used in tattooing (see p. 446).^{204,205} The skin lesions are sometimes limited to certain areas of a tattoo where a particular pigment has been used.²⁰⁵ Two patterns are seen – a foreign body type and a sarcoid type.²⁰⁶ In the latter form, there are aggregates of epithelioid histiocytes and giant cells with a sparse perigranulomatous round cell infiltrate. The histiocytes and giant cells contain pigment particles. True sarcoidosis has also been reported in tattoos, in some cases associated with pulmonary hilar lymphadenopathy. Some of these cases may represent a generalized sarcoid-like reaction to tattoo pigments rather than true sarcoidosis.^{207,208} Other granulomatous complications of tattoos include tuberculosis cutis and leprosy.²⁰⁹

Sarcoidal granulomas may occur as a rare complication of ear piercing. It is not always a consequence of the trauma/scarring but may represent a contact allergy to nickel and other metals.²¹⁰

Zirconium compounds used in underarm deodorants and other skin preparations have been associated with a granulomatous skin reaction in sensitized individuals.^{211,212} Histologically, the lesions are identical to sarcoidosis. Usually no birefringent material is seen in polarized light. In one case of a reaction to an aluminum–zirconium complex, foreign body granulomas and birefringent particles were seen as well as tuberculoid-type granulomas.²¹³ Ophthalmic drops containing sodium bisulfite have been implicated in the formation of pigmented papules on the face. The papules were caused by sarcoidal granulomas with brown-black pigment in foreign body giant cells.²¹⁴

Sarcoidal granulomas have been reported at the injection sites of interferon – both IFN- β -1b, used in the treatment of multiple sclerosis,²¹⁵ and IFN- α -2a, used in the treatment of hepatitis C.²¹⁶

In the past, cutaneous granulomatous lesions with histology similar to sarcoidosis have been reported in persons exposed to beryllium compounds in industry.^{217,218} Other foreign bodies capable of inducing sarcoidal granulomas include acrylic and nylon fibers, wheat stubble, and sea urchin spines.^{219–221} Sea urchin spines can produce all types of granuloma, not just sarcoidal ones. The nature of the granulomatous reaction that followed the use of hydroxyurea is uncertain. It may have been sarcoidosis.²²²

Occasionally, keratin from ruptured cysts or hair follicles can induce sarcoidal granulomas rather than the more usual foreign body type of reaction.

TUBERCULOID GRANULOMAS

Although the granulomas in the tuberculoid group consist of collections of epithelioid histiocytes, including multinucleate forms, they tend to be less circumscribed than those in the sarcoidal group, have a greater tendency to confluence, and are surrounded by a substantial rim of lymphocytes and plasma cells. Langhans giant cells tend to be more characteristic of this group, but foreign body-type giant cells are also seen. There may be areas of caseation in the lesions of tuberculosis.

Tuberculoid granulomas are seen in the following conditions:

- Tuberculosis
- Tuberculids
- Leprosy
- Fatal bacterial granuloma
- Late syphilis
- Leishmaniasis
- Rosacea
- Idiopathic facial aseptic granuloma
- Perioral dermatitis
- Lupus miliaris disseminatus faciei
- Crohn's disease.

In addition to these diseases, tuberculoid granulomas, some with central necrosis, have been described at injection sites of protamine–insulin, as a hypersensitivity reaction to protamine. One case, consisting of both tuberculoid and sarcoidal granulomas, followed Q fever vaccination.²²³ The granulomas occurring in the homolateral limb after previous mastectomy, although described as sarcoidal, were more of a tuberculoid nature.²¹

TUBERCULOSIS

Typical tuberculoid granulomas can be seen in the dermal inflammatory reaction of late primary inoculation tuberculosis, late miliary tuberculosis, tuberculosis cutis orificialis, tuberculosis verrucosa cutis ('prosector's wart'), scrofuloderma, and lupus vulgaris.²²⁴ Cutaneous tuberculosis is discussed in detail with the bacterial infections (see p. 650). A similar pattern of inflammation can be seen after BCG vaccination and immunotherapy.^{225,226}

Histopathology

Santa Cruz and Strayer have stressed the variety of histological changes seen in cutaneous tuberculosis.²²⁷ In many forms, particularly in early lesions, there is a mixture of inflammatory cells within the dermis that includes histiocytes and multinucleate cells without well-formed epithelioid granulomas. The changes seen in the overlying epidermis are variable. In some forms, inflammatory changes extend into the subcutis. Areas of caseation may or may not be present within granulomas. In some cases, this may be difficult to distinguish from the necrobiosis seen in rheumatoid nodules (see p. 205). The number of acid-fast organisms varies in different lesions. In lesions with caseation, organisms are most frequently found in the centers of necrotic foci.²²⁸ Generally, where there are well-formed granulomas without caseation necrosis, organisms are absent or difficult to find. Neutrophils may be a component of the inflammatory infiltrate, and abscesses form in some clinical subtypes. Both Schaumann bodies and asteroid bodies can occasionally be present in multinucleate giant cells.

In lesions with caseation and demonstrable acid-fast organisms, the histological diagnosis may be straightforward. In lupus vulgaris, however, caseation necrosis, if present, is minimal and organisms are rarely found. Evidence of mycobacterial infection may be determined by PCR techniques.²²⁹

Differential diagnosis

There is usually a heavier round cell infiltrate about tuberculous granulomas than is seen in sarcoidosis. It is to be remembered that the small foci of fibrinous material that sometimes are seen in the granulomas of sarcoidosis may mimic and be mistaken for caseation. Epidermal changes and dermal fibrosis are not commonly part of the histopathology of sarcoidosis.

Lesions of other nontuberculous mycobacterial infections of the skin, such as those due to *M. marinum*, may be histologically indistinguishable from cutaneous tuberculosis. Organisms are usually difficult to find in *M. marinum* infections; they are described as being longer and broader than typical *M. tuberculosis*. Culture or PCR is required for species identification.

The combination of marked irregular epidermal hyperplasia, epidermal and dermal abscesses, and dermal tuberculoid granulomas may be seen in tuberculosis verrucosa cutis, caused by *M. tuberculosis*, and in swimming pool granuloma due to *M. marinum* infection. This reaction pattern is also seen in cutaneous fungal infections such as sporotrichosis, chromomycosis, and blastomycosis. Diagnosis depends on identification of the appropriate organism.

The lesions of tuberculosis cutis orificialis must be distinguished from those of oral or anal Crohn's disease and from the Melkersson–Rosenthal syndrome (see p. 210). This is not always possible on histological grounds and may depend on clinical history and associated lesions. Foci of caseation and acid-fast organisms may be seen in tuberculous lesions. Marked edema and granulomas related to or in the lumen of dilated lymphatic channels are present in the Melkersson–Rosenthal syndrome.

TUBERCULIDS

The tuberculids are a heterogeneous group of cutaneous disorders associated with tuberculous infections elsewhere in the body or in other parts of the skin (see p. 653). They include lichen scrofulosorum, papulonecrotic tuberculid, and erythema induratum–nodular vasculitis. Although it has previously been thought that organisms are not found in tuberculids, recent PCR studies have demonstrated mycobacterial DNA in some cases (see p. 653).²²⁹

In *lichen scrofulosorum*, there is a superficial inflammatory reaction about hair follicles and sweat ducts that may include tuberculoid granulomas. Acid-fast organisms are not usually seen or cultured from the lesions.²³⁰ Caseation is rare.²³¹

Histopathological studies of *papulonecrotic tuberculid* have shown a subacute or granulomatous vasculitis and dermal coagulative necrosis with, in some cases, a surrounding palisading histiocytic reaction resembling granuloma annulare.²³² Acid-fast bacilli are not found in the lesions. Tuberculoid granulomas were not described in one study²³³ but have been recorded in others.²²⁴

In *erythema induratum–nodular vasculitis*, there is a lobular panniculitis, although tuberculoid granulomas usually extend into the deep dermis (see p. 535).

LEPROSY

Tuberculoid granulomas are seen in the tuberculoid (TT), borderline tuberculoid (BT), and borderline (BB) groups of the classification of

Figure 7.4 Leprosy. The tuberculoid granuloma is elongated along the course of a nerve in the deep dermis. (H&E)

leprosy introduced by Ridley and Jopling.²³⁴ Leprosy is considered further on page 658.

Histopathology²³⁵

In *tuberculoid leprosy* (TT), single or grouped epithelioid granulomas with a peripheral rim of lymphocytes are distributed throughout the dermis and subcutis. Unlike lepromatous leprosy, this infiltrate does not spare the upper papillary dermis (grenz zone), and it may extend into and destroy the basal layer and part of the stratum malpighii. The granulomas are characteristically arranged in and around neurovascular bundles and arrectores pilorum muscles. Granulomas, particularly in the deeper parts of the infiltrate, tend to be oval and elongated along the course of the nerves and vessels (Fig. 7.4). Small cutaneous nerve bundles are infiltrated and enlarged by the inflammatory cells. There may be destruction of nerves, sometimes with caseation necrosis that may mimic cutaneous tuberculosis. In contrast, the infiltrate in tuberculosis is not particularly related to nerves. The granulomas in tuberculoid leprosy may contain well-formed Langhans-type giant cells and less well-formed multinucleate foreign body giant cells. The causative organism, *M. leprae*, which is best demonstrated by modifications of the Ziehl–Neelsen stain such as the Wade–Fite method, is usually not found in the lesions of tuberculoid leprosy. Rare organisms may be present in nerve fibers. PCR has been used to demonstrate DNA of *M. leprae* in lesions.¹⁶

Granulomas in the *borderline tuberculoid form* (BT) are surrounded by fewer lymphocytes, contain more foreign body giant cells than Langhans cells, and may or may not extend up to the epidermis. Organisms may be found in small numbers or not at all. Nerve bundle enlargement is not so prominent, and there is no caseation necrosis or destruction of the epidermis.

In the *borderline form* (BB), the granulomas are poorly formed and the epithelioid cells separated by edema. Scant lymphocytes are present about the granulomas, and there are no giant cells. Nerve involvement is slight. Organisms are found, usually only in small numbers.

FATAL BACTERIAL GRANULOMA

This condition was first reported in the English literature in 2002 under the title ‘fatal bacteria granuloma after trauma: a new entity’.²³⁶ The cases were reported from rural China. They were characterized by spreading, dark red plaques that followed slight trauma to the face.

The patients had severe headache and clouding of consciousness during the later stages of the disease. All patients died within 1.5–4 years.

Electron microscopy demonstrated two types of bacteria: one was an anaerobic actinomycete, which was sensitive to lincomycin (a fore-runner of clindamycin), and the other organism was a *Staphylococcus*. The unknown actinomycete was regarded as the probable causative agent.²³⁶ One paper reported finding *Propionibacterium acnes*, which seems unusual.²³⁷ A recent publication described the culture and sensitivity results from 21 cases of fatal bacterial granuloma following facial and eyelid trauma. Twenty-two strains of anaerobic *P. acnes* were isolated from these patients. Sensitivity studies showed that these strains were resistant to metronidazole but sensitive to ciprofloxacin, penicillins, and a variety of other agents; combinations of antimicrobials were recommended for treatment.²³⁸

Histopathology

The epidermis was normal and there was a heavy, diffuse dermal infiltrate of cells, mainly histiocytes. In addition there were lymphocytes, plasma cells, neutrophils, and many multinucleated giant cells in some areas. There was vascular occlusion with focal hemorrhage and necrosis in the deep dermis.²³⁶

LATE SYPHILIS

Some lesions of late secondary syphilis and nodular lesions of tertiary syphilis show a superficial and deep dermal inflammatory reaction in which there are tuberculoid granulomas (see p. 677).²³⁹ Plasma cells are generally but not always prominent in the inflammatory infiltrate, and there may be swelling of endothelial cells.^{240,241} One study found that a plasma cell infiltrate and endothelial swelling, traditionally associated with syphilis of the skin, are in fact infrequently seen in biopsies.²⁴² Organisms are rarely demonstrable in these lesions.

LEISHMANIASIS

In chronic cutaneous leishmaniasis (see p. 750) and leishmaniasis recidivans, tuberculoid granulomas are present in the upper and lower dermis.²⁴³ The overlying epidermal changes are variable. Occasionally, the granulomas extend to the basal layer of the epidermis as in tuberculoid leprosy.²⁴⁴ Necrosis is not usually seen in the granulomas.²⁴⁵ Leishmaniae are usually scarce but may be found in histiocytes or, rarely, free in the dermis. The organisms have sometimes been mistaken for *Histoplasma capsulatum* but differ from the latter in having a kinetoplast.

ROSACEA

Rosacea is characterized by persistent erythema and telangiectasia, predominantly of the cheeks but also affecting the chin, nose, and forehead (see p. 500). The lacrimal and salivary glands were affected in one case.²⁴⁶ In the papular form, papules and papulopustules are superimposed on this background. Tuberculoid granulomas are seen in the granulomatous form, which may present as a solitary plaque mimicking Morbihan's disease or solid facial edema of rosacea.²⁴⁷ Granulomatous rosacea has been reported in children as well as adults and also in association with infection with HIV.^{248–250} Granulomatous rosacea can be found in most clinical variants of rosacea.²⁵¹ A rosacea-like granulomatous eruption developed in an adult patient using tacrolimus ointment in the treatment of atopic dermatitis.²⁵² Granulomas may be a response to *Demodex* organisms or lipids.^{253,254} Granulomas have also been described in the lesions of pyoderma faciale, thought to be an extreme form of rosacea.²⁵⁵

Figure 7.5 Granulomatous rosacea. Tuberculoid granulomas are present in the dermis. There is some telangiectasia of vessels in the superficial dermis. (H&E)

Histopathology²⁵⁶

The changes seen in biopsies of the papules are variable and relate to the age of the lesion. Early lesions may show only a mild perivascular lymphocytic infiltrate in the dermis. In older lesions, there is a mixed inflammatory infiltrate related to the vessels or to vessels and pilosebaceous units. The infiltrate consists of lymphocytes and histiocytes with variable numbers of plasma cells and multinucleate giant cells of Langhans or foreign body type. In some lesions, epithelioid histiocytes and giant cells are organized into tuberculoid granulomas (granulomatous rosacea) (Fig. 7.5).²⁵⁷ An acute folliculitis with follicular and perifollicular pustules and destruction of the hair follicle is sometimes seen. This corresponds to the perifollicular variant of granulomatous rosacea described by Sánchez *et al.*²⁵¹ Granulomatous inflammation may be centered on identifiable ruptured hair follicles. At other times, the granulomas are distributed diffusely through the dermis.²⁵¹ There is dermal edema and vascular dilatation. Epidermal changes, if present, are mild and nonspecific.

In granulomatous rosacea, the granulomas are usually of tuberculoid type and not the 'naked' granulomas of sarcoidosis (see p. 192). Changes resembling caseous necrosis may be present, associated with a histiocytic reaction. In one series, necrosis was present in 11% of cases.²⁴⁸ Differentiation from lupus vulgaris may be difficult. In some cases of rosacea, the inflammatory changes may be related to damaged hair follicles. The presence of marked vascular dilatation is suggestive of rosacea.

IDIOPATHIC FACIAL ASEPTIC GRANULOMA

Thirty cases of this unusual granulomatous condition of the face, also termed *pyodermite froide du visage*, have been reported from a single center in France.^{258,259} All cases occurred in children, with a mean age of 3.8 years. The children presented with one or several acquired painless nodules on the face, lasting for at least 1 month. There was no response to antibiotics, and no infectious agent was demonstrated. It was suggested that the disease might belong to the spectrum of childhood rosacea.²⁵⁹ A granulomatous response to an embryological residue was also considered.²⁵⁹ In recent years, additional examples have been reported, including cases from Italy, Spain, and the United States.^{260–263} The putative association with rosacea has been based on both the microscopic features and the frequent association with conjunctivitis and chalazia.^{260,261}

Histopathology
